differences, as well as age, developmental stage, and previous experience need to be taken into account. Many children will have already become aware that something is seriously wrong from changes in their parents’ mood or behavior. From as young as 7, children may associate the diagnosis of cancer with the threat of dying. Not talking about this connection does not protect children from anxiety. Children’s behavioral reactions to bad news may belie their feelings. Thus, withdrawal and lack of upset or angry challenging behavior does not necessarily indicate indifference or lack of sympathy or empathy. Parents diagnosed with cancer or other serious illnesses should be offered help to think about whether, what, and how to tell their children about their illness, and about what the children can understand, especially as the parents may be struggling themselves to come to terms with their illness. In the first instance, this is most appropriately led by the clinicians involved with the illness, but guidance or even direct involvement of mental health professionals may be of particular benefit. Involving the healthy parent (or another carer) in the discussions is important (Forrest *et al.*, 2006, 2009).

Young carers and parental psychiatric and physical illness

It is estimated that large numbers of children provide informal (and unpaid) care for parents with either physical or psychiatric disorders. This is a common and underrecognized concern, and is especially important in chronic illnesses where children often take on a range of physical and medical caring roles as well as providing emotional support for their parents (Becker, 2007). In sub-Saharan Africa, a much higher proportion of young children with parents who have physical or psychiatric illnesses are involved in care, largely because of the lack of social or health care support (Becker, 2007). Very large numbers of children are looking after sick and dying relatives and at a much younger age, often with older siblings going out to work. Children’s roles can include, for example, accompanying for medical appointments, collecting and administering medication, bathing and toileting their unwell parent (Cluver *et al.*, 2012), as well as high levels of housework and, in low-resource settings, earning money to support the family (Bauman *et al.*, 2006). A number of reports (e.g., Aldridge *et al.*, 2003) rightly stress that each family and presentation is different, and that the carer role is not always detrimental to the child’s well-being. Nonetheless, there are important potential difficulties and risks for a child required to take on a caring role. These include missing out on school and developing peer relationships, absent or inconsistent parental support and discipline, as well as having anxiety about their parent’s health and fearing separations for either hospital admission or because their parent is terminally unwell. It has been argued that when children have to play these roles in the context of parental depression, they are at particular risk of psychological disturbance (Radke-Yarrow *et al.*, 1994). The involvement of the healthier parent or carer can be vital for children. Strengthening families to care for such vulnerable

children and strengthening community responses is critical (Richter *et al.*, 2009; Betancourt *et al.*, 2011).

Concluding comments in relation to both parental physical and psychiatric disorders

Health care professionals should always enquire about whether patients have children, their well-being, and the extent to which they are involved in care of the parent. Hospitals and other clinical facilities should provide space and facilities to allow children to visit and spend time with their parents. Emotional support for such children is critical. Advice on how and where they can obtain help and liaison with social services to provide practical support in the home is invaluable. Where “young carer” groups exist, these can provide emotional support and respite.

Summary

In summary, there is evidence that parental psychiatric and physical disorders are associated with a range of psychological and physical sequelae in children. However, it is crucial to be aware that children are not invariably adversely affected, and the outcomes emanating from and mechanisms through which parental psychiatric disorder may affect outcomes for children are heterogeneous. Recent research has moved from assuming traditional causal models to process-orientated models, whereby the aim is to understand why an association exists between parent risk and child outcome (mediation) and under what conditions the risk may be accentuated or ameliorated (moderation). A number of high-quality intervention studies have informed both clinical practice and policy; however, much remains to be done to improve child outcomes and support families. Furthermore, much can be learnt from children who thrive despite adversity, and a focus on resilience is critical for the future (see Chapter 27).

Finally, it is important to note that much of the burden of the impact of parental psychiatric disorder falls in LMICs. However, most of the research on parental psychiatric disorder has been conducted in high-income settings, with uncertainty about the applicability of these findings across different LMIC settings. Much less research, especially treatment trials, has been conducted in LMICs, and this omission needs to be rectified (Patel *et al.*, 2011).

Safeguarding children: a pressing global challenge

Child maltreatment is a prevalent risk factor associated with later illness, socio-economic disadvantage, and crime (Gilbert *et al.*, 2009b). Worldwide, many children are exposed to abusive or neglectful experiences that violate their rights (Pinheiro, 2006). Some of these children die as a result of maltreatment, while many more develop psychiatric and medical disorders, at significantly higher rates than non-maltreated children. The detrimental health consequences of child maltreatment are not limited to the childhood years. Rather, they can endure well into adult life (Danese *et al.*, 2009). Maltreated children are not only at high risk of adult psychiatric and medical disorders but may also respond more poorly to traditional treatment (Nanni *et al.*, 2012). Even when they do not develop diagnosable disorders, they often suffer significant distress and impairment in cognitive, social, and emotional development and functioning. In addition, individuals with a history of childhood maltreatment often have poorer educational achievements, lower earnings, and higher risk of engaging in criminal activities compared to non-maltreated individuals (Currie & Widom, 2010). Because child maltreatment is associated with significant personal and societal costs, prevention, identification, and treatment of child maltreatment cases should be conceptualized not only as a moral responsibility but also as an urgent economic target.

However, protecting children remains a challenging task for several reasons. First, simply trying to define maltreatment can be difficult given the variations in boundaries around parenting practices and the variation in norms and attitudes about violence across cultures and across generations. Clarity of definitions is important to ensure recognition of maltreatment cases. Second, professionals may be challenged by the diversity of the theoretic

cal frameworks used to understand acts of abuse and neglect of children. Child protection work necessarily involves the close collaboration of professionals with backgrounds in medicine, psychology, education, social work, law, law enforcement, and policy. Harmonization of knowledge from these diverse fields is crucial, in order to promote interdisciplinary work. Finally, professionals may find it difficult to make sense of the complex and diverse nature of the consequences associated with maltreatment. Better understanding of how child maltreatment relates to these various outcomes is important to promote effective interventions for maltreated children (Shonkoff *et al.*, 2009).

Child protection also represents a significant challenge for governments worldwide. Maltreatment of children continues to occur in all societies and possibly more frequently in low- and middle-income countries (Pinheiro, 2006). To affirm universal children's rights, the 1989 United Nations (UN) Convention on the Rights of the Child sets a legal framework for implementing policy, accountability, and social justice. This UN Convention emphasizes that the best interest of the child is paramount. Rights across three main areas were established. First, children have rights of protection, including the right to be protected from any form of maltreatment or exploitation resulting in threats to their survival, development, or well-being. This implies that effective prevention should be a primary focus. Second, children have rights of participation, including the right to be actively involved in decisions and actions affecting them. Finally, children have rights of provision, including the right to education and the obligations of the state to support families. Although nearly every government worldwide has ratified the UN Convention on the Rights of the Child, its practical implementation remains incomplete in several countries. Furthermore, resources dedicated to child protection are insufficient in most countries.

Definitions: maltreatment types

The World Health Organization (WHO) has defined child maltreatment as: "... all forms of physical and/or emotional ill treatment, sexual abuse, neglect or negligent treatment or commercial or other exploitation, resulting in actual or potential harm to the child's health, survival, development or dignity in the context of a relationship of responsibility, trust or power" (Krug *et al.*, 2002). However, it is widely acknowledged that such a concise definition belies a complex issue that can vary in relation to the victim's age and identity, the motivation and actions of the perpetrator and the cultural context. Four primary types of child maltreatment will be reviewed here (Butchart *et al.*, 2006); other forms of child maltreatment (e.g., child trafficking, children exposed to combat, etc.) are beyond the scope of this chapter.

Sexual abuse has been defined as "... forcing or enticing a child or young person to take part in sexual activities, not necessarily involving a high level of violence, whether or not the child is aware of what is happening" (UK DoE, 2013). Sexual abuse can include activities that involve physical contact (e.g., touching, kissing, and penetration), non-contact activities (e.g., involving children in looking at, or in the production of, sexual images), child sexual exploitation (e.g., prostitution), and grooming (in England).

Physical abuse of a child has been defined as the intentional use of physical force (often to inflict punishment) against a child "... that results in—or has a high likelihood of resulting in—harm for the child's health, survival, development, or dignity" (Butchart *et al.*, 2006). This includes a variety of acts, such as hitting, beating, kicking, shaking, biting, strangling, scalding, burning, poisoning, and suffocating. The definition includes fabricated or induced illness in the United Kingdom (UK DoE, 2013), while the US definition requires threat of harm (U.S. DHHS, 2010). Domestic corporal punishment is classified as unlawful and regarded as physical abuse in twenty-nine countries but remains lawful (albeit controversial) in several countries, including England, Australia, and the United States of America.

Emotional and psychological abuse has been defined as: "the persistent emotional maltreatment of a child such as to cause severe and persistent adverse effects on the child's emotional development" (UK DoE, 2013). It may involve conveying to a child that they are worthless, unloved, or inadequate, not giving the child opportunities to express their views, or imposing developmentally-inappropriate expectations on children. England, the United States of America and Canada include exposure to domestic violence within their definitions of emotional abuse (Munro *et al.*, 2011); in addition, the United States of America and Canada have a separate category on witnessing violence (U.S. DHHS, 2010). In England, serious bullying and cyber-bullying are included in the definition of emotional abuse (UK DoE, 2013).

Neglect has been defined as "The persistent failure to meet a child's basic physical and/or psychological needs, likely to result in the serious impairment of the child's health or development" (UK DoE, 2013). Neglect may relate to a failure to provide adequate nutrition, shelter, protection from harm or access to medical care or treatment. In England and Canada, reference is also made to failure to adequately supervise a child, which has the potential to lead to harm (Munro *et al.*, 2011).

Epidemiology

The exact prevalence of child maltreatment varies depending not only on the definition used but also on the method of assessment, namely self-reports of victims who are old enough to participate in surveys; parent-reports on child abuse or neglect and patterns of care; or official statistics from statutory agencies (e.g., child protection services and police).

Several community studies based on self- and parent-reports have been undertaken to study the prevalence of various maltreatment types in high-income countries (Gilbert *et al.*, 2009b). The cumulative prevalence of any *sexual abuse* in community studies ranges between 15% and 30% in girls and between 5% and 15% in boys, while the cumulative prevalence of penetrative sexual abuse ranges between 5% and 10% in girls and between 1% and 5% in boys. The cumulative prevalence of *physical abuse* ranges between 5% and 35%. The cumulative prevalence of *emotional abuse* ranges between 4% and 9%. In addition, 10–20% of children and adolescents witness intimate-partner violence in their homes. The cumulative prevalence of *neglect* ranges between 6% and 12% in the United Kingdom and United States of America. In contrast to these high prevalence figures from community studies, official reports showed that only 5% of children are referred to social welfare in the United Kingdom and in the United States of America, and that 0.3–1% of children were substantiated as cases of maltreatment. Among the substantiated cases, neglect is by far the most common form of maltreatment (44–60%), followed by emotional abuse (11–23%), physical abuse (10–15%), and sexual abuse (7%).

A community study by the UK National Society for the Prevention of Cruelty to Children (NSPCC) found that nearly 1 in 5 children (18.6%) experience some forms of maltreatment (Radford *et al.*, 2011). Consistent with previous studies, the NSPCC survey showed that children who experienced one form of maltreatment were 2–3 times more likely to also experience other forms of maltreatment and to be victimized by other perpetrators over time. The evidence of such poly-victimization, namely the recurrent and cumulative nature of different types of maltreatment, emphasizes the importance of secondary prevention strategies in child protection (Finkelhor *et al.*, 2007a, b).

Despite these high prevalence estimates, evidence suggests that some forms of maltreatment may have decreased over the past two decades, although this topic remains hotly debated (Gilbert *et al.*, 2012; Radford *et al.*, 2012; Finkelhor & Jones, 2012). It should be noted that the prevalence of child abuse

codes from hospitalized children has not declined in the same period. In contrast to the downward trends for sexual and physical abuse (62% and 56% decline, respectively), data indicated a relatively stable prevalence of neglect (10% decline) over the past two decades (Olson & Stroud, 2012).

Factors associated with occurrence of maltreatment

Although several risk factors show a statistical association with maltreatment, it is often unclear whether such factors have a causal role in its occurrence. Making inferences about causality is complicated by a number of issues. To begin with, several factors associated with maltreatment (e.g., a child's behavior problems, parents' mental illness, and poverty) are correlated, that is, they tend to co-occur, and it may be difficult to isolate causal elements within a complex mixture of correlated factors in observational studies. Advances in this area have been aided by the development of multilevel, ecological models encompassing individual, family, and community risk factors (Belsky, 1993), and by the recognition of the bidirectional interaction between individual factors in children and their parents/carers (Bell, 1968). A peculiar form of bidirectional interaction is the genetic predisposition to environmental exposure, or gene-environment correlation (Jaffee & Price, 2007). For example, children may inherit from their parents a predisposition to exhibit problem behaviors, which in turn may increase the odds of evoking harsh parenting. An additional challenge to causal inference is that risk factors for maltreatment are non-deterministic, that is, no single risk factor is either necessary or sufficient for maltreatment to occur. For example, although parental mental illness is a risk factor for child maltreatment, most parents with mental illness do not abuse their children and most maltreated children do not have parents with mental illness (Kaufman & Zigler, 1987; Dixon *et al.*, 2005). Different risk factors could be conceptualized as component causes that interact with each other and with protective factors in linear or non-linear fashion. Therefore, risk of maltreatment is likely to be more accurately predicted by examining a comprehensive set of risk and protective factors. The available evidence provides a framework for the informed clinician to make judgments about children most likely to be at risk and target resources appropriately. The following risk factors may help identify children at risk of maltreatment and maltreatment recurrence (Goldman *et al.*, 2003).

Child's individual risk factors for victimization

A number of child-specific factors have been associated with increased risk of being maltreated. The presence of such factors does not imply that the child holds any responsibility for their maltreatment; rather, such factors can be understood as potentially aggravating other parental, family, and community

risk factors for perpetration. Some of these risk factors could be targeted by interventions to reduce the risk of maltreatment or its recurrence. Young children (age 5 and younger) are disproportionately represented among reported cases of maltreatment and cases of death due to maltreatment (U.S. Child Welfare, 2013), presumably because of their physical vulnerability, developmental immaturity, and more dependent relationship with carers. However, teenagers are at greater risk for sexual abuse both from family members and from strangers. Other characteristics of the child that increase strain for the parents or carers have also been associated with greater maltreatment risk, including broadly defined disability (Jones *et al.*, 2012), and difficult temperament or problem behaviors.

Parents' or carers' individual risk factors for perpetration

Maltreatment may be more likely when parents or carers struggle to understand the needs of the developing child or to modulate their own behavior accordingly. For example, young age of parent, low education, inaccurate knowledge of child development, unrealistic expectations of their children and impaired capacity for empathy have all been linked to elevated risk of maltreatment (Zeanah & Zeanah, 1989; Dixon *et al.*, 2005). Furthermore, elevated risk of maltreatment has been associated with impaired emotion regulation in parents, as manifested through both emotional symptoms (e.g., low self-esteem, neurotic personality, and depression) and behavior problems (e.g., impulsive behavior and substance abuse). As child maltreatment predicts several of these risk factors in adult life (see below), it is not surprising that parents' own history of maltreatment is, in turn, associated with elevated risk of maltreatment perpetration.

Family risk factors

Heightened maltreatment risk has been linked to a constellation of inter-related factors that increase strain on the family, including large family size, single parenthood, non biological transient carers in the home and intimate-partner violence (Finkelhor *et al.*, 2007b). Furthermore, maltreatment risk is greater in families that cannot access support because of social isolation (Crouch *et al.*, 2001), socio economic disadvantage, or lower levels of education (Brown *et al.*, 1998).

Community risk factors

In addition to individual and family factors, maltreatment risk is also influenced by the broader context in which children and their families live. Child maltreatment cases are concentrated in more impoverished neighborhoods and research suggests that poverty and unemployment are particularly associated with risk of neglect and physical abuse, with mixed evidence in relation to sexual abuse (Coulton *et al.*, 1995). Community violence and collective efficacy (i.e., mutual trust among neighbors and willingness to intervene on behalf of the common good) may

also contribute to maltreatment rates (Sampson *et al.*, 1997). These distal factors may be associated with more proximal risk factors, such as unstable housing, childcare burden, greater strain on families, and attitudes toward violence.

Consequences of maltreatment

The most tragic and widely publicized consequence of maltreatment is death due to deliberate acts of physical or sexual abuse or severe neglect. Despite the likely under-reporting owing to insufficient investigation of child deaths in most countries, WHO estimated that 155,000 deaths in children younger than 15 years occur worldwide every year as a result of abuse or neglect, which is 0.6% of all deaths and 12.7% of deaths due to any injury (Pinheiro, 2006). Homicide occurs most frequently during infancy but also peaks in adolescence, largely at the hands of biological or step-parents (UNICEF, 2003).

Child maltreatment has also been associated with a variety of consequences for health, wealth, and crime. However, establishing the causal mechanisms linking maltreatment with these outcomes remains challenging. On the one hand, because maltreatment is not randomly distributed in the population but rather clusters with other risk factors, maltreated individuals

differ from non-maltreated individuals in relation to several other characteristics in addition to maltreatment. These differences may represent confounds that, in turn, bias the interpretation of the effects of maltreatment. On the other hand, several studies have investigated the association of retrospective reports of childhood maltreatment with various outcomes, introducing the possibility that outcome status could influence the recall of maltreatment (recall bias) and that an apparent outcome may have actually preceded maltreatment exposure (selection bias). When weighing the strength of the available evidence, it is therefore important to consider whether studies have adequately considered the presence of co-occurring risk factors, report findings consistent with those observed in animals randomly exposed to early life stress and report results consistent with longitudinal-prospective investigations (Danese & Tan, 2014).

Figure 29.1 lists the range of phenomena associated with child maltreatment. First, child maltreatment has been associated with a variety of physical health problems. The most consistent effects observed in longitudinal-prospective studies are arguably in relation to obesity (Gilbert *et al.*, 2009b; Danese & Tan, 2014). In addition, cross-sectional and case-control studies also showed elevated risk for several chronic medical conditions in maltreated compared to non-maltreated adults. Second, child maltreatment has been associated with a variety of mental

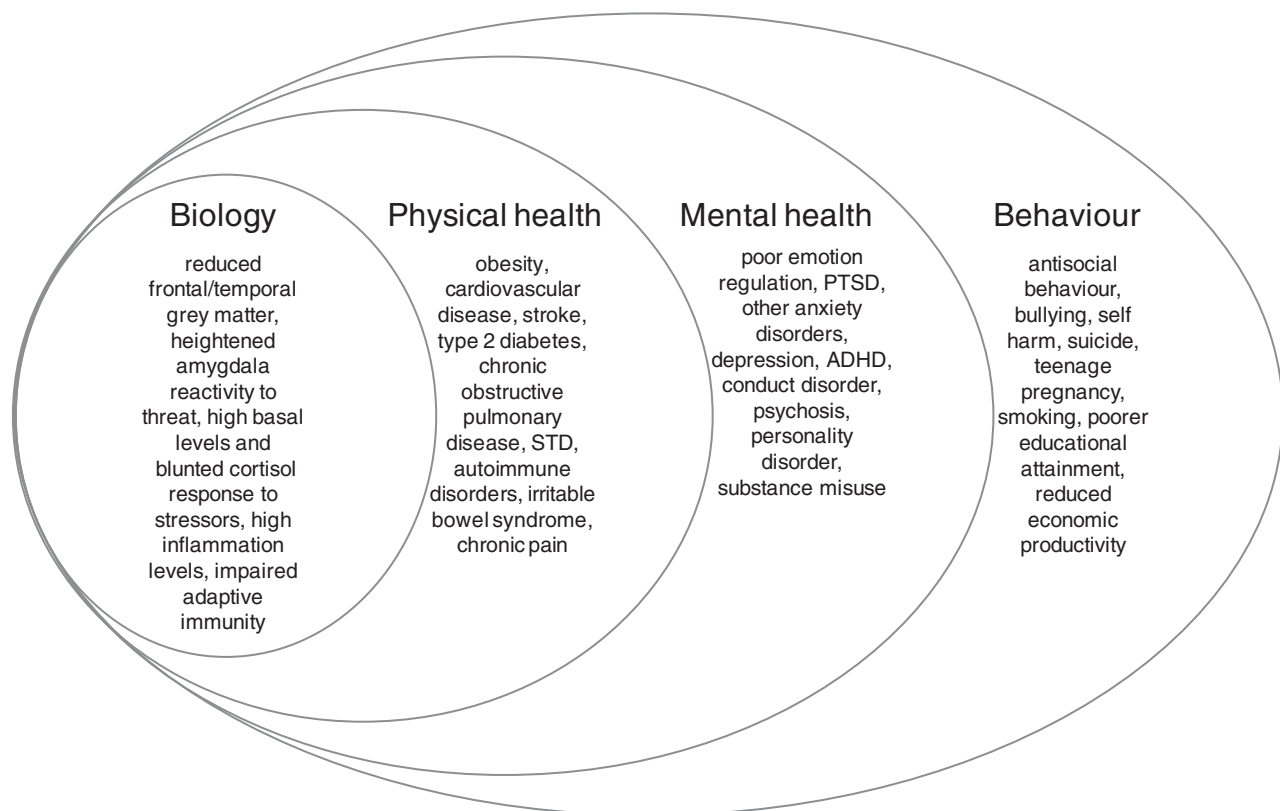

Figure 29.1 Biological/psychological/medical consequences of maltreatment in children and adults exposed to maltreatment in childhood.

health problems, both in childhood and adult years. Because of its enduring effects, it is possible that maltreatment could affect not only the risk of psychiatric disorders but also their longitudinal course (Nanni *et al.*, 2012). Third, child maltreatment has been associated with poor educational achievement and economic productivity (Currie & Widom, 2010). Finally, child maltreatment has been associated with violence, antisocial behavior, and criminal offenses. It is important to stress that such outcomes are associated with only a minority of children who experience abuse, but they are important in understanding the risk of inter-generational cycles of violence that characterize some families (Dodge *et al.*, 1990).

The experience of being maltreated often co-occurs with a range of familial disadvantages and can impact development at a number of levels. Psychologically, children commonly experience feelings of powerlessness and shame and internalize their experiences to signify that they are neither valued nor loved. Over time, such feelings can contribute to patterns of low self-esteem and negative self-schemata, reducing a sense of self-efficacy and increasing vulnerability to psychopathology. Exposure to poor or erratic physical and emotional boundaries and a failure of adults to help the child reflect on their own emotions and social behavior can lead to poor socialization and manifest as disorganized or insecure attachment patterns. This absence of normative “emotional scaffolding” by carers, paired with a sense that adults are a source of danger rather than protection, can create an experience of chronic stress that also impacts at the biological level (McCrory *et al.*, 2010; Danese & McEwen, 2012). Studies of the biological mechanisms through which maltreatment affects clinical outcome (or “biological embedding”) have the potential to identify latent neurobiological risk factors that may shed light on the ways in which clinical symptoms emerge. For example, at the structural level, maltreated children compared to typically developing peers show reduced gray matter volume in a number of brain regions, including frontal and temporal regions. The reduced volume of the orbitofrontal cortex in particular may represent a neural basis for possible deficits in social and cognitive functioning (Hanson *et al.*, 2010; De Brito *et al.*, 2013). At the functional level, maltreated children show heightened reactivity to threat cues in the amygdala (McCrory *et al.*, 2011), even when these are presented subliminally (McCrory *et al.*, 2013), suggesting increased vigilance to social threat in their environment. Consistent with this, it has been shown that maltreated children generally show higher basal (unstimulated) levels of the stress-hormone cortisol and blunted cortisol response to psychosocial stress tasks or pharmacological challenges (Danese & McEwen, 2012). They also have been reported to show higher circulating levels of inflammation proteins and impaired adaptive immune response to pathogens (Shirtcliff *et al.*, 2009; Danese *et al.*, 2011). Although such biological adaptations may confer short-term benefits, for example, in increasing vigilance in the face of threat, they are likely to incur longer-term costs, ultimately increasing vulnerability to psychiatric and medical disorder (McCrory & Viding, in press;

Danese & McEwen, 2012). Indeed, compared to non-maltreated adults, adults with a history of maltreatment continue to show alterations in brain structure and function (McCrory *et al.*, 2010; Danese & McEwen, 2012) and persistent abnormalities in endocrine and immune functioning (Heim *et al.*, 2000; Danese *et al.*, 2007). Such biological changes may be brought about by the molecular effects of stress on the biochemical composition of a child’s DNA, or epigenetic changes (Chapter 25), which may affect expression of key regulatory genes (Meaney, 2010).

Further research is required to establish if the association between child maltreatment and biological abnormalities or clinical outcomes is sensitive to the type of maltreatment considered or to the timing of maltreatment, although preliminary evidence suggests that earlier timing might lead to more detrimental effects (Andersen & Teicher, 2008; Tottenham *et al.*, 2010; McCrory *et al.*, 2011; McCrory *et al.*, 2013). Consistent with the cumulative effects of other life stressors (McEwen, 1998), different types of maltreatment at different ages may exert cumulative effects on biology and health (Felitti *et al.*, 1998; Danese *et al.*, 2007). Clinically, maltreated children are commonly exposed to multiple types of maltreatment with repeated experiences over time and such chronicity is a strong predictor of poor outcomes (Finkelhor *et al.*, 2007a, b; Radford *et al.*, 2011; Jonson-Reid *et al.*, 2012). Therefore, identification of independent effects of specific forms of maltreatment is difficult in epidemiological and clinical studies, and distinctions may be artificial.

Finally, it is important to emphasize that the aforementioned studies largely looked at differences between groups of maltreated and non-maltreated children. However, there are broad individual differences within groups of maltreated children, many of whom do not develop some or indeed any of these outcomes. Child-level, family-level, and community-level factors may act to increase or reduce resilience in the face of adversity (Cicchetti, 2013). For example, there is ample evidence that genetic influences may affect an individual’s sensitivity to environmental stressors, such as maltreatment, and their likelihood of developing depression (Caspi *et al.*, 2010). Furthermore, a more flexible personality style, a warm and loving relationship with parents and more secure attachments, positive peer relationships in adolescence, and positive romantic relationships in adulthood could reduce the risk of developing adult psychopathology after child maltreatment (Jaffee *et al.*, 2007; Collishaw *et al.*, 2007).

Recognizing child maltreatment

The discrepancies in maltreatment prevalence estimates based on official statistics and on self-/parent-reports suggest that child protection referrals account for only a fraction of maltreatment cases. Training in child protection may address these discrepancies by increasing recognition and reporting (Jones *et al.*, 2008). Recognition and reporting may also be increased by reducing structural barriers and empowering young people

to make self-referrals through voluntary organizations, such as ChildLine in the United Kingdom and the Italian Telefono Azzurro.

Data from Europe and the United States of America has shown that schools contribute a large proportion of the child protection cases referred to professionals, followed by law enforcement agencies, social services, and health professionals (Gilbert *et al.*, 2009a). Although referrals by health professionals constitute only a minority of the overall number, these often relate to the children who have experienced the most severe forms of abuse and present with injuries and symptoms.

Mental health professionals should be vigilant of the possibility of maltreatment while working with children and families who present with some of the risk characteristics outlined in the section “Factors associated with occurrence of maltreatment.” For example, increased risk of maltreatment has been associated with parental substance/alcohol misuse, mental health problems, history of violent offending, own history of maltreatment, cruelty to animals, young age, low education, poor understanding of child development, unrealistic expectations, and lack of empathy. Equally, a child’s disability, difficult temperament, and problem behaviors may also increase risk of being a victim of maltreatment.

Recognizing maltreatment often requires health professionals to piece together information from different sources and agencies and from their own assessment (NICE, 2009). During their assessment, professionals should observe a child’s appearance and behavior, their interaction with parents and signs and symptoms. They should also listen carefully to the history reported and particularly to any reports or disclosures of maltreatment. Systematic reviews of the literature on the validity and discriminatory ability of various possible signs of maltreatment (Kempe *et al.*, 1962) have informed guidelines to improve recognition of child maltreatment by health professionals. For example, in the United Kingdom, the National Institute for Health and Care Excellence (NICE) has produced a list of features that should prompt professionals to consider or to suspect maltreatment (see Table 29.1) (NICE, 2009). Similar guidelines have also been developed in the United States of America by the American Professional Society on the Abuse of Children (APSAC) and the US Child Welfare/US Department of Health & Human Services (U.S. Child Welfare, 2007; Myers & APSAC, 2010). Professionals should seek an explanation for observed injuries or presentations, speaking to carers and to the child and any siblings (if appropriate), as well as collecting collateral information. Because recognition of maltreatment is generally more difficult in children with disability, professionals should seek support from colleagues with relevant expertise in these circumstances. Professionals should then consider if they have been provided with a suitable explanation for the alerting features they identified. For example, explanations may be unsuitable when they are implausible or inadequate. Explanations may also be unsuitable when they are inconsistent with a child’s developmental stage, normal activities, or medical

Table 29.1 NICE guidelines on recognition of child maltreatment.

Emotional abuse
Age-inappropriate behavior, aggression, body rocking, change in emotional or behavioral state, cutting, dissociation, drug taking, eating and feeding behavior, encopresis, fearful, runaway behavior, self-esteem, self-harm, sexual behavior, smearing (feces) and wetting
Physical abuse
Abrasions, bites (human), bruises, burns, cold injuries, cuts, eye injuries, fractures, hypothermia, intra-abdominal injuries, intracranial injuries, intrathoracic injuries, lacerations, ligature marks, oral injuries, petechiae, retinal hemorrhage, scalds, scars, spinal injuries, strangulation, subdural hemorrhage and teeth marks
Sexual abuse
Anal symptoms and signs, anogenital injuries, dysuria, foreign bodies, genital symptoms and signs, pregnancy, sexual exploitation, sexualized behavior (also see Emotional, behavioral, interpersonal and social functioning), sexually transmitted infections (STIs) and vaginal discharge
Neglect
Abandonment, bites (animal), clothing, dirty child, failure to thrive, faltering growth, footwear, head lice, health promotion, health reviews, home conditions, immunization, lack of provision, lack of supervision, medication adherence, parental interaction with medical services, persistent infestations, poor hygiene, scabies, screening, smelly child, sunburn and tooth decay

condition, or when they are inconsistent between different people or over time. Professionals should discuss their conclusions with experienced colleagues, such as pediatricians, child and adolescent mental health professionals, and designated members of staff with experience in child protection. Based on the information gathered, professionals may decide to exclude the occurrence of maltreatment, or to suspect it and, thus, to act to address their concerns (see section “Responding to child maltreatment”).

It is common for mental health professionals to find themselves in a delicate position where they not only work with children and their families but also contribute to multi-agency child protection work. Clinical dilemmas related to confidentiality, divided loyalty and professional responsibility are common in everyday practice. First, professionals should make clear from the beginning that they cannot necessarily keep information about risk of significant harm to young patients, their siblings or other people as confidential (UK DoE, 2008). Rather, they have a duty to take action, including, where necessary, disclosing relevant confidential information to statutory agencies. Second, professionals working with both children and their parents may have a sense of divided loyalty as they may have professional responsibilities to both parties. However, all professionals should be mindful that the child’s interest is always paramount, as they are more vulnerable. Finally, professionals may believe that the person or agency with whom they shared their concerns have not acted on them appropriately. In this case, they should follow up their concerns and take them to the next level of authority.

To document actions and improve clarity of communication, it is important that professionals keep clear, accurate, comprehensive and contemporaneous notes, reporting what they have observed and heard from whom and when, what is of concern in their opinion, and what action they have taken. They should also follow up oral communications with other professionals in writing.

Responding to child maltreatment

Decisions about how best to respond to maltreatment concerns involve a degree of risk, particularly when signs of abuse or neglect are not clear-cut and the evidence is ambiguous. At one extreme, there is a risk of leaving the child in a harmful environment. At the other extreme, there is a risk of removing the child unnecessarily from the family. In general, it is important that mental health professionals do not ignore warning signs because risk to children may only become apparent when several professionals express even minor concerns on the same child or family.

When professionals recognize signs of abuse or neglect or consider maltreatment as a possible explanation for a child's clinical presentation or unmet needs, they should initially discuss their concerns with their manager and with a designated member of staff with experience in child protection. If concerns persist, it is also possible to discuss them with senior colleagues from other agencies, including social services, without disclosing the identity of the child or family.

If concerns about child maltreatment persist after discussion, professionals must refer the case to statutory agencies, such

as the local authority social services (other statutory agencies are the police and, in the United Kingdom, the National Society for the Prevention of Cruelty to Children, or NSPCC), and follow up in writing. If the child is already known to the agency, the allocated social worker should be informed of the concerns.

Referrals to social services should be discussed with the children and their parents in order to seek their agreement. Children should be involved in this process as appropriate for their competence and understanding, and through open discussion without leading questions that may jeopardize later police investigation. These discussions with parents and children help ensure that children's rights to protection and participation and parents' right to family life are respected. Moreover, they are an important means to build trust and collaboration. If children or parents refuse to give consent, professionals should assess whether the possible benefits of sharing information outweigh those of keeping the information confidential. Furthermore, professionals may decide not to seek consent if they believe that this would place the child at significant risk of increased harm.

Referral to social services prompts responses that may differ based on the legal and administrative frameworks set in different countries but overall adhere to common principles. They are discussed here with reference to the UK child protection procedures (UK DoE, 2013).

Following a referral, social services (or other statutory agencies) make a rapid assessment of the child's needs and risks to plan initial actions. At one extreme, where risk is deemed to be low, social services may decide that the child's needs could be addressed through universal and targeted services supporting parents (e.g., parenting programs, assistance with mental health

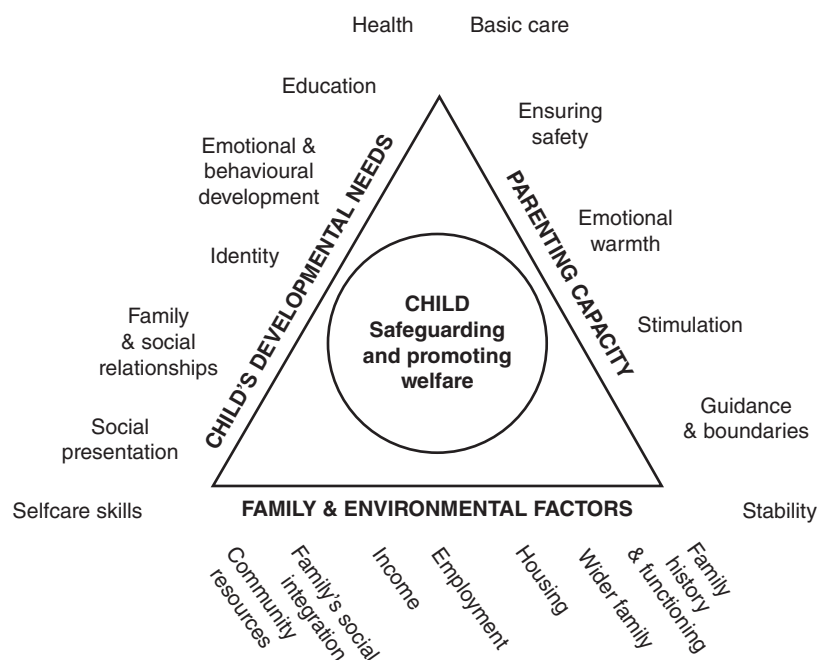

Figure 29.2 Family assessment framework triangle.

problems). At the other extreme, where risk is deemed to be immediate and life-threatening, social services may decide that it is in the child's best interest to be removed from the family and placed elsewhere (e.g., under section 20 or section 31 of the UK Children Act 1989). However, most cases are not clear-cut and require further investigation.

Many cases involve children found in the initial assessment to be "in need," that is (according to the UK Children Act 1989), children who are unlikely to achieve or maintain a satisfactory level of health or development, who are disabled or asylum seeker, or whose parents are in prison. In these cases, social services are mandated to undertake a multidisciplinary, holistic assessment of the child's needs in the context of their family and wider community ("core" assessment, under section 17 of the UK Children Act 1989). The Common Assessment Framework (CAF, Figure 29.2) (UK DoE, 2012) remains a helpful tool for this assessment, guiding the comprehensive evaluation of the child's developmental needs (including whether they are suffering or likely to suffer significant harm), parenting capacity, and family environment. Tools used to further evaluate these areas include the Strengths and Difficulties Questionnaire (Goodman, 1997), the Family Assessment (Bentovim & Bingley, 2001), and the HOME inventory (Cox & Walker, 2002), respectively. The assessment typically considers the needs of the child in relation to the capacity and motivation of the parents or carers to meet those needs, in order to evaluate potential for remediation and set objectives for subsequent interventions.

During initial or "core" assessment, evidence may emerge leading the social worker to suspect that the child is suffering or likely to suffer significant harm. There are no absolute criteria by which significant harm can be judged, but decisions in this area involve a consideration of the effect of any ill treatment on the child's overall physical and psychological health and development. In these circumstances, social services are mandated to investigate further by convening a multi-agency discussion (strategy meeting) and, if significant risk is identified, by undertaking further enquiries (under section 47 of the UK Children Act 1989), along with law enforcement investigation by the police. The findings from these investigations are discussed in multi-agency meetings (child protection conference) and, if future risk to a child is likely, a tailored child protection plan is put in place and reviewed periodically to monitor progress.

Interventions

As discussed earlier, child maltreatment is not a disorder but rather an exposure to an adverse experience or set of experiences during development. Therefore, safeguarding interventions are best conceptualized not as treatment of child maltreatment but rather as prevention of recurrence (i.e., re-exposure to maltreatment) or impairment (i.e., clinical symptoms) linked to maltreatment (MacMillan *et al.*, 2009).

Prevention of recurrence of child maltreatment

Interventions in this category are generally carried out under the auspices of child protection services in collaboration with different professionals and agencies. The first aim of any intervention is to ensure safety for the maltreated child (and the non-abusing parent in cases of domestic violence), working with the family whenever possible or removing the child (and siblings) from severely abusive or neglectful families. In order to identify the most effective elements for intervention in a particular case of maltreatment, it is important to recognize the particular strengths and vulnerabilities of the individual child and the family during the assessment phase. Although exposure to a single type of maltreatment is unusual, interventions nevertheless commonly focus on one prevailing type of maltreatment. Parent-child interaction therapy (PCIT) has been shown to reduce the recurrence of physical abuse but not neglect, according to child protection services reports (Chaffin *et al.*, 2004). Limited evidence supports the use of parent-training programs to prevent recurrence of physical and emotional abuse (Barlow *et al.*, 2006). For example, parenting programs such as 'The Incredible Years' have been shown to be effective in reducing abusive parenting in maltreating families (Letarte *et al.*, 2010). A large cluster randomized trial showed that a structured, home-based behavioral-skill training program (SafeCare) was associated with reduction in neglect recurrence over the 6 years of follow-up (Chaffin *et al.*, 2012). Limited evidence from small studies suggests that resilient-peer training, imaginative play, therapeutic day training, and multisystemic therapy might reduce recurrence of neglect. One program of intensive nurse visitation failed to prevent recurrence of physical abuse or neglect (MacMillan *et al.*, 2005). A number of studies addressed prevention of maltreatment recurrence by investigating the effect of foster care (MacMillan *et al.*, 2009). Compared to children who remained at home, fostered children often showed better behavioral and educational outcomes. Furthermore, a remarkable randomized trial of postinstitutionalized children showed that foster care placement could remediate the detrimental effects of early deprivation on cognition in institutionalized children (Nelson *et al.*, 2007).

Prevention and treatment of impairment

Interventions targeting mental health needs are generally carried out by child and adolescent mental health services. Because not all children exposed to maltreatment develop psychiatric disorders and maltreatment may lead to different psychiatric disorders (see Figure 29.1), it is important to identify psychopathology and levels of clinical symptoms and everyday functioning during the assessment phase. Systematic review (Ramchandani & Jones, 2003) and meta-analysis (Macdonald *et al.*, 2006) of this literature suggested that Trauma-Focused Cognitive-Behavioral Therapy is effective in treating sexually abused young people with post-traumatic stress disorder, anxiety, and depressive symptoms, but is not effective in treating externalizing disorders symptoms or sexualized behavior.

Effective components of Trauma-Focused Cognitive-Behavioral Therapy after child sexual abuse include psycho-education, relaxation, affect modulation, cognitive restructuring, trauma narrative and in vivo exposure modules for young people, and also seek active involvement of parents (Cohen *et al.*, 2006). In addition, there is preliminary evidence supporting the efficacy of short-term community-based interventions for mothers and children exposed to interpersonal violence, in relation to both behavior problems and emotional symptoms (Graham-Bermann *et al.*, 2007).

Prevention of maltreatment occurrence

Over the last two decades, there has been an increasing focus on evaluating the effectiveness of universal and targeted approaches to prevent the occurrence of childhood maltreatment (MacMillan *et al.*, 2009). Universal approaches include public awareness and education campaigns as well as more practically focused programs that aim to improve parenting practices. While universal approaches are applied to whole communities, targeted approaches are delivered specifically to high-risk groups such as low-income first time mothers.

Universal interventions

Evidence supporting the effectiveness of universal approaches has generally been limited. However, there is preliminary but strong evidence from one randomized controlled trial (RCT) of the Positive Parenting Program (or Triple P) professional training alongside a media and communication strategy (Prinz *et al.*, 2009). The RCT found that compared to the services-as-usual control condition, areas where Triple P was delivered showed significant reductions in rates of substantiated cases of child maltreatment, child out-of-home placements, and child maltreatment injuries after two years of dissemination.

Education programs delivered in school represent another universal approach—typically targeting the prevention of sexual abuse by covering themes such as identifying potential abuse situations, differentiating “good touch” from “bad touch” and how and whom to tell if abuse has occurred. One recent systematic review summarized the evidence from 15 RCTs or quasi RCTs that tested programs aiming to teach children about sexual abuse and how to protect themselves from it (Zwi *et al.*, 2007). Although these programs were found to be generally effective in improving knowledge and protective behaviors, studies have been characterized by a number of methodological weaknesses, such as lack of blinding and short follow-up periods. In addition, some studies have reported negative outcomes, including increased anxiety. Most crucially, however, there is as yet no evidence that increased knowledge translates into actual reduction in risk of sexual abuse (Zwi *et al.*, 2007).

Targeted interventions

Targeted home-visitation programs, such as the Nurse Family Partnership and Early Start, have been shown to be effective

in preventing child maltreatment in several studies (Dodge & Coleman, 2011). Visitation programs vary in their models of delivery, focus and practitioner training.

The Nurse Family Partnership (NFP) is probably the most rigorously evaluated example, having undergone three RCTs with high retention rates in different samples in the United States, both in urban and semi-rural areas. Nurses visit low-income first-time mothers during pregnancy and into infancy in order to develop a trusting relationship with the mother and other family members and to promote sensitive parenting. The program aims to ensure prenatal and postnatal health of the child and to improve the mother’s economic self-sufficiency (MacMillan *et al.*, 2009). Three published trials have reported reductions in emergency department visits, fewer cases of child abuse and neglect in the whole sample after a 15-year follow-up (Olds *et al.*, 1997), fewer health-care encounters (Kitzman *et al.*, 1997), and preliminary evidence of an overall reduction in the likelihood of child death by age 9 years. However, the positive effects of the NFP intervention were not observed in families where moderate-to-high levels of intimate partner violence were reported (Eckenrode *et al.*, 2000).

The Early Start program is an intensive home-visiting program targeted at families experiencing stress that includes an assessment of the family’s needs and resources, a collaborative problem solving approach and provision of support and advice. The intervention aims to improve child health, reduce risk of abuse, and improve parenting, relationship stability, and material well-being. There is preliminary support that this program is associated with lower hospital attendance for childhood injuries and lower parent-rated physical abuse (Fergusson *et al.*, 2005). RCTs evaluating home visiting programs employing paraprofessionals have overall been less effective (Geeraert *et al.*, 2004).

Future directions

Although there is an increasing appreciation of the negative impact of maltreatment on children across a range of outcomes, there remain significant gaps in our understanding of the underlying causal mechanisms and of best practice in this context.

Prevention of child maltreatment remains the priority for all professionals involved in safeguarding. The need for effective preventive interventions is emphasized, for example, by the continuing high prevalence of different types of maltreatment, by the severity of its immediate potential consequences, by the lack of knowledge about the ability of treatment to remediate biological abnormalities before the onset of clinical conditions, and by the poor outcomes of clinical conditions in maltreated individuals. Future preventive interventions will need to explore the value of new conceptual approaches. For example, the idea of “blending” universal and targeted approaches aims to improve matching the intensity of interventions with the severity of a

family's risk profile (Prinz *et al.*, 2009). Furthermore, the idea of "common elements" aims to identify the components shared by different effective interventions and to improve matching these components with the family's risk profile (Chorpita *et al.*, 2007; Bentovim & Elliot, 2014). Finally, the "New Orleans Model" aims to improve the initial phase of assessment and intervention for families with children in foster care, in order to more clearly establish the potential for remediation in parents, to promptly achieve a permanent plan of reunion or adoption, and to minimize risk of maltreatment recurrence (Zeanah *et al.*, 2001). While prevention of child maltreatment is a pressing priority, it will be crucial to rigorously evaluate promising preliminary findings before dissemination.

Despite the efforts promoting prevention, it is naïve to assume that child maltreatment can be easily or entirely eradicated from society. Therefore, it is equally important to ensure that as clinicians we are effective in recognizing, responding to, and alleviating the consequences of maltreatment. Research emphasizes two important directions that have the potential to significantly impact on future clinical care.

Research suggests that focus should be placed not only on clinical conditions but also on preclinical vulnerabilities that are evident at the biological level in community samples of maltreated children (Danese *et al.*, 2011; McCrory & Viding, *in press*). However, the current configuration of health services is centered on the identification and treatment of clinical conditions, with few tools or resources deployed to identify and help those children at elevated risk for future problems. Even in the absence of clinical conditions, it appears that maltreated children show stress-related biological changes that confer what has been conceptualized as 'Latent Vulnerability' for future disorders (McCrory & Viding, *in press*). To the extent that they predict disease risk and could be remediated, preclinical biomarkers represent missed opportunities for the design of effective therapeutic and secondary-preventative interventions. Longitudinal research is required to isolate and identify risk markers that could be incorporated into routine clinical practice. Furthermore, clinical trials are needed to test whether currently available interventions are effective in modifying clinically relevant biological abnormalities (Fisher *et al.*, 2007; Dozier *et al.*, 2008; Pace *et al.*, 2013).

Finally, research on the mechanisms of biological embedding of early life stress suggests that the potential consequences of maltreatment may go far beyond the traditionally recognized psychological symptoms and also impact physical health in children and adults (Danese *et al.*, 2009; Danese & McEwen, 2012). Stress-related endocrine and immune abnormalities in maltreated children could increase risk of medical conditions, such as obesity (Danese & Tan, 2014) and inflammatory/immune disorders (Dube *et al.*, 2009), as well as cardiovascular disease and other age-related disorders in later life (Dong *et al.*, 2004; Danese *et al.*, 2009). However, children's liability to non-acute medical conditions is often overlooked in clinical practice. To the extent that alleviation of trauma-related psychological

symptoms could remediate the biological liability to medical conditions, an integrative brain/body approach to assessment and treatment may significantly improve outcomes of maltreated children.

CHAPTER 30

Child sexual abuse

Danya Glaser

Department of Child and Adolescent Psychiatrist, Great Ormond Street Hospital for Children, London, UK

Introduction

While child sexual abuse (CSA) involves the child in a physical act, its deleterious consequences are primarily psychological. It is a significant risk factor for the development of psychopathology in childhood, adolescence and adulthood.

CSA may be the explicit reason for referral to CAMHS (child and adolescent mental health services), but may also be discovered incidentally during assessment or treatment, especially when common sequelae are encountered. At times, an unsolicited disclosure is made by a child during therapeutic work. Child psychologists, psychiatrists, and psychotherapists may contribute to investigations of CSA, particularly in assessment interviews of young or very traumatized children, or in children with communication difficulties. Consultation to social services in case management and to caregivers of children who have been sexually abused is often requested. Risk assessments of adolescent abusers may also be required. It is therefore of importance to CAMHS.

The hallmarks of CSA are its secret nature and the very frequent denial of alleged abuse by the abuser. Sexual abuse extends beyond incest, occurring both within and outside the family but the abuser is frequently already known to the child. Indeed this acquaintance may follow a deliberate befriending or “grooming” of the child by the abuser.

CSA is not a new phenomenon. General Booth, founder of the Salvation Army, wrote in 1890: “I understand that the Society for the Protection of Children prosecuted last year a fabulous number of fathers for unnatural sins with their children” (Booth, 1890). However, CSA only began to be noted as a significant form of child maltreatment in the 1970s. Increasing recognition came with the development of the women’s movement, reports by women survivors of their childhood abuse and a greater openness regarding sexuality. There have been

successive reports from many countries in the scientific press, in particular in *Child Abuse and Neglect, the International Journal*.

In the United Kingdom and many other jurisdictions, disapproval of CSA is expressed by the legal prohibition of incest and sexual contact between an adult and a child. However, some of the harmful effects of child sexual abuse are largely consequent on societal disapproval. Despite the high frequency of CSA reports (see later), most suspicions of sexual abuse continue to be met with caution, and disclosures are often regarded with suspicion. This is probably explained by the social taboo surrounding adult sexual contact with children, the absence of noninvolved witnesses to this (secret) activity and the potentially serious consequences for the alleged abuser if found guilty. Thus the rates of criminal prosecution and conviction are low (Hagborg *et al.*, 2012) and lower in comparison with other crimes (Cross *et al.*, 2003).

Controversy has surrounded disputed memories of childhood sexual abuse recovered in adulthood, (Davies & Dalglish, 2001). Some memories have returned spontaneously whereas others have been triggered by reminders or recalled in response to enquiry that include leading questions and other forms of suggestion (Loftus *et al.*, 1994; see also Chapter 20). A few have been induced by over-zealous therapists. While this debate has (inappropriately) rekindled doubts about the general truth of allegations made by children, there has now been recognition of considerable magnitude of CSA outside the family by clergy and media persons who have gained access to children.

Definitions

A myriad of definitions for legal, research and other purposes continue to be used. A recent definition guiding child protection work in England states: “Sexual abuse involves forcing or enticing a child or young person to take part in sexual activities, not necessarily involving a high level of violence, whether or not the

child is aware of what is happening. The activities may involve physical contact, including assault by penetration (for example, rape or oral sex) or non-penetrative acts such as masturbation, kissing, rubbing and touching outside of clothing. They may also include noncontact activities, such as involving children in looking at, or in the production of, sexual images, watching sexual activities, encouraging children to behave in sexually inappropriate ways, or grooming a child in preparation for abuse (including via the internet). Sexual abuse is not solely perpetrated by adult males. Women can also commit acts of sexual abuse, as can other children” (Department for Education, 2013). The United Nations Committee on the Rights of the Child (UNCRC, 2011) in its General Comment 13 (a detailed guidance on Article 19 which deals with violence against children) has the following definition: “Sexual abuse and exploitation includes: (a) The inducement or coercion of a child to engage in any unlawful or psychologically harmful sexual activity. Sexual abuse comprises any sexual activities imposed by an adult on a child against which the child is entitled to protection by criminal law. Sexual activities are also considered as abuse when committed against a child by another child, if the child offender is significantly older than the child victim or uses power, threat or other means of pressure. Sexual activities between children are not considered as sexual abuse if the children are older than the age limit defined by the State party for consensual sexual activities; (b) The use of children in commercial sexual exploitation; and (c) The use of children in audio or visual images of CSA; (d) Child prostitution, sexual slavery, sexual exploitation in travel and tourism, trafficking (within and between countries) and sale of children for sexual purposes and forced marriage. Many children experience sexual victimization which is not accompanied by physical force or restraint but which is nonetheless psychologically intrusive, exploitive and traumatic.” It is important to note that the abuser’s intentions or motivations are not considered necessary to be included in definitions.

The term pedophilia applies to a sexual attraction to, and arousal by prepubertal children, of either gender. It is clear that many sexual abusers are therefore not pedophiles.

Cultural aspects

Culturally sanctioned and normative practices may be harmful (McKee, 1984) and “cultural practice ... should not justify hurting a child or young person” (National Institute for Health and Care Excellence (NICE), 2009). A particular example of harmful cultural practice is female genital mutilation (Powell *et al.*, 2004), which is regarded as a clear form of child abuse in many jurisdictions.

Legal considerations

The differences between the civil – family and child protection law and criminal law are pertinent to CSA. The threshold for a criminal prosecution, which is solely concerned with the

innocence or guilt of the alleged abuser, is higher than that required for the civil legal protection of the child.

In some jurisdictions, such as in England and the United States of America, civil and criminal proceedings can continue in parallel and independently of each other. Thus, a child may be protected from an abuser by being moved from his care under civil law, when there has been no criminal trial, or a failed prosecution. In other jurisdictions, child protective procedures will only follow a criminal conviction of the abuser; the CRC definition (see earlier) refers to the criminal law. This confers considerably less protection for children, especially as the rate of convictions worldwide is low relative to the number of allegations.

Demographics

The victims

Age of victims

Children may be abused from infancy onwards but frequency and severity increase with age (Finkelhor *et al.*, 2009; Radford *et al.*, 2011).

Gender of victims

Girls are more commonly victims of sexual abuse than boys. There is a tendency for sexual abuse of boys to be under-reported (Holmes & Slap, 1998), in part because of shame and the fear of homosexuality. Extrafamilial abuse more commonly involves boys although there is no agreement about whether boys are more commonly abused by strangers (Watkins & Bentovim, 1992).

Disability

The rate of sexual abuse of children with disabilities is 2 or 3 times greater than in “normal” children (Sullivan & Knutson, 2000), the reasons for this including: the children’s difficulties in communicating about abuse (Morris, 1999); their dependency on intimate physical care; social isolation in institutional care (Utting *et al.*, 1997); and care by staff rather than parents (Westcott & Jones, 1999).

Abusers

Adults

Sexual abusers constitute a heterogeneous group in terms of personal, social, and demographic factors. The majority of abusers (85–95%) are male. Men in old age may well continue to abuse children. Pedophiles, who abuse prepubertal children, may target both boys and girls (Strassberg *et al.*, 2012). A small proportion of CSA is carried out by female abusers (Saradjian, 1996), often in conjunction with a man. Women abusers on their own are more likely to abuse boys (Faller, 1989). There is no unitary psychological profile of abusers. Moreover, whereas many will have experienced disruption and physical abuse in their formative years, sexual abuse in childhood is only one

predisposing factor (summarized in Watkins & Bentovim, 1992) and is not a prerequisite to sexual abuse.

Children and adolescents

Sexual abuse by both children and adolescents, mostly boys, has become widely recognized and is no longer considered an acceptable variant of childhood or adolescent sexual development. A significant proportion of adolescent abusers are of low intellectual ability and show heterogeneous maladaptive mental schemata regarding social interaction and abuse (Richardson, 2005). Most children and adolescents who sexually abuse other children have experienced psychosocial adversity. They include material neglect, lack of supervision, sexual abuse by a female person and witnessing intrafamilial violence (Salter *et al.*, 2003), discontinuity of care, and experience of physical violence and emotional abuse (Skuse *et al.*, 1998). Sixty six per cent of contact sexual abuse reported by children and young people in the United Kingdom was perpetrated by other children and young people under the age of 18 (Radford *et al.*, 2011).

Many adult abusers report the onset of their abusive activities in adolescence and abuse by an adolescent cannot necessarily be considered safely to “burn out” in adulthood (Vizard *et al.*, 1995). However, there is evidence of good response to treatment of adolescent abusers (see later).

Abuser–child relationship

The majority of children know their abuser and abuse by strangers is rare. However, the abuser may befriend the child as part of the grooming process, or the abuser and child may be part of the same family, or social network. In community studies, the commonest relationship is step-father – step-daughter (Finkelhor, 1984). The same abuser may abuse children both within and outside the family and include biological as well as step-children. Intrafamilial abuse continues for longer than sexual abuse outside the family, and some forms, such as parent-child abuse, have more serious and lasting consequences (Finkelhor, 1994.)

The nature and circumstances of the abuse

Frequency and duration of abuse for an individual child

Whereas some population studies include a majority with a single episode of abuse, for many children and in clinical samples there has been repeated abuse by the same abuser, often continuing for several years.

Contact abuse

Broadly, any physical contact between the breasts and genitalia of a child or adult and a part of the other's body, with the exception of isolated accidental touch or for developmentally- and age-appropriate cleaning or for applying medication or ointment, is considered to be sexual abuse. It includes fondling,

masturbation, oral-genital contact or penetration, attempted or actual digital and penial penetration of, and the insertion of objects into, the vagina or anus. There is, typically, a gradual progression from touching to more penetrative abuse (Berliner & Conte, 1990), so as to avoid causing initial pain or injury which would be more likely to lead the child to complain about or report the abuse. Anal abuse is understandably commoner in boys, although younger girls are not infrequently anally abused (Hobbs & Wynne, 1989). In a small proportion of cases, actual physical violence is used, either as a way of intimidating or coercing the child, or as an integral aspect of the abuse.

Noncontact abuse

This includes deliberate exposure of children to adult genitalia or sexual activity, either live or depicted in photographs or film. It also includes intrusive looking at the young person's body, inducing children to interact sexually with each other and taking photographs for pornographic purposes. Although the most serious effects of sexual abuse are associated with contact, and especially penetrative, abuse, many young persons report the experience of being intrusively observed as humiliating and intimidating, with greater coercion increasing the harm.

The use of the internet and mobile phone technology

The internet and mobile phone technology have become sources of sexual abuse of children by a number of different ways (Taylor & Quayle, 2003). Children may view pornographic images inadvertently or by deliberately searching for them. This exposure is increasing (Wolak *et al.*, 2006) and is reported by children as very disturbing (Finkelhor *et al.*, 2000). The internet is also increasingly used by adults in a variety of ways (CEOP, 2013) including requests for children's pictures of themselves or for grooming with the intention of luring children into sexual activity (O'Connell, 2003). In addition, children are being made the subjects of abuse images (Palmer, 2005). Lastly, child pornography may act as a motivator or reinforcer of sexually abusive activity by adolescents (Quayle & Taylor, 2006). Children are also distributing images of themselves and of other children captured on mobile phones. As with other forms of sexual abuse, children and adolescents are often reluctant to talk about this activity, which may be discovered in the course of criminal investigations regarding material found on computers, rather than disclosed by the child.

Organized abuse

Most abusers abuse in isolation. However, there are also organized forms of abuse involving more than one abuser and multiple children, some of whom are recruited in sex rings (Wild & Wynne, 1986). Some adolescents are being targeted on the basis of their vulnerability, for example, living in care and institutions. Organized abuse also includes the use of children and young persons for the production of child pornography. Questions remain about the reliability, verifiability, and

credibility (Young *et al.*, 1991) of the reports of formalized rituals (Frude, 1996).

Commercial sexual exploitation of children

Commercial sexual exploitation or “transactional sex” (Williams *et al.*, 2012), involving both boys and girls, takes the inter-related forms of prostitution and trafficking – usually across borders (Chase & Statham 2005). While an accurate scale of the problem is difficult to determine (Dottridge, 2008), it is likely to be global and increasing with economic hardship (ECPAT International, 2009). Sexual exploitation can provide a source of money to support drug dependency and introduces the young person to addictive drugs as a means of gaining control over them for subsequent sexual exploitation.

Abuse by clergy, media personnel, and in institutions

Sexual abuse by clergy and media personnel has come to light in a number of countries including the United Kingdom, Ireland, the United States of America and Australia. It includes abuse of both single and multiple victims, across the age-range and of both genders (Haywood *et al.*, 1996), although boys were over-represented (Parkinson *et al.*, 2012). Finkelhor (2003) mentions negative as well as some positive consequences including increased public belief in the existence of CSA; enabling more children and adolescents to talk of their own abuse; lessening the stigma of sexual abuse for boys; and recognition of corporate or organizational responsibility for employees’ behavior.

Children in residential settings are particularly vulnerable, being dependent on staff and often isolated from confiding contact with adults outside the residential setting (Utting *et al.*, 1997).

Epidemiology

Published figures for incidence and prevalence of CSA vary considerably according to the definition used, the source of data, and the population studied. Whereas broad definitions point to the extent of the problem, they are less helpful in indicating severity and the kind of therapeutic services required.

Prevalence

The most accurate prevalence figures are from population studies (Finkelhor *et al.*, 1990). Even here, responses to interviews or questionnaires may be underestimates, due to reluctance to report, or a lack of recall of previous abuse, even when this had been documented at the time (Williams, 1994).

In population, as opposed to victim samples, nonpenetrative contact abuse is more commonly described than in clinical samples. A meta-analysis of self-report studies across a number of countries (Andrews *et al.*, 2004) found the following prevalence rates (see Table 30.1).

Table 30.1 Prevalence rates of sexual abuse.

	Girls (%)	Boys (%)
Any sexual abuse	25.3	8.7
Contact abuse	13.2	3.7
Penetrative abuse	5.3	1.9

In a retrospective study using a questionnaire with a random probability sample of 18–24 years olds in the United Kingdom (May-Chahal & Cawson, 2005) 10% reported experiencing contact sexual abuse while under 16 years of age (15% girls and 6% boys). A retrospective study from the United States, using a mailed questionnaire to a national geographically stratified, random sample of 1442 subjects with mean age 46 years (range of 18–90) yielded a response by 64.8% and 32.3% female and 14.2% male respondents reported childhood sexual abuse. Rates of abuse within the immediate or extended family (46.8%) and penetrative abuse (52.8%) did not differ according to gender of subject (Briere & Elliott, 2003). Prevalence rates of maltreatment including CSA were reported in a recent large random probability sample from the United Kingdom, in which there were interviews with parents of children under the age of 11 years, children aged 11–17 and their caregivers, and young adults aged 18–24, respectively (Radford *et al.*, 2011). Percentage of contact and overall, including noncontact, sexual abuse in the samples was reported as follows (see Tables 30.2 and 30.3).

Considerable co-occurrence of different forms of maltreatment is reported in many of these studies.

Fluctuations in rates of reported cases

Rates of reporting increased over the 20 years after 1970, both in the United Kingdom (Markowe, 1988) and in the United States of America (Finkelhor, 1991) probably due to increased awareness with little evidence that the actual incidence had been changing significantly (Feldman *et al.*, 1991). However, the number of substantiated cases of CSA in the United States

Table 30.2 Percentage contact child sexual abuse experienced by age.

AGE (years)	<11	11–17	18–24
Girls (%)	0.8	7	17.8
Boys (%)	0.2	2.6	5.1
Total (%)	0.5	4.8	11.3

Table 30.3 Percentage overall child sexual abuse experienced by age.

AGE (years)	<11	11–17	18–24
Total (%)	1.2	16.5	24.1

of America has decreased by an estimated 49% between 1990 and 2004 with fewer disclosures, confessions by abusers and a reduction in emotional and behavioral problems associated with CSA (Finkelhor & Jones, 2006). A similar finding, of declining rates of sexual abuse of males over some decades and of females more recently, has been reported from Australia (Dunne *et al.*, 2003) and a possible decline in substantiated cases in Canada (Collin-Vézina *et al.*, 2010) and the United Kingdom (see Radford *et al.*, 2011 above). There could be several reasons for these findings: (a) an actual decline (Finkelhor & Jones, 2004) possibly signaling a positive effect of interventions for reported CSA; growing awareness of children's rights or greater vigilance and child-focused parenting; (b) a decline in reporting due, for instance, to fear of legal repercussions or (c) changes in agency responses to reported abuse, such as increased cautiousness and a raised threshold for an active professional response. It is likely that this decline in substantiated cases of sexual abuse reflects some actual reduction in incidence.

Country, ethnicity, culture, socioeconomic, and family status

CSA is now reported from most, including developing countries (e.g., Luo *et al.*, 2008) with some 5% of children in sub-Saharan Africa reportedly experienced penetrative sexual abuse in childhood (Lalor, 2004).

Within the United Kingdom and the United States of America, population-based studies have shown no ethnic differences in the rates of CSA (Fontes, 1995). However, data on CSA incidence in minority and different ethnic communities are lacking, partly due to decisions on data collection criteria, which do not classify racial/ethnic background sufficiently finely, and partly because shame and denial about sexual abuse within some minority cultures conspire against reporting. Incidence within a particular ethnic group may reflect effects of that group's recent traumatic and migration experiences, rather than aspects of the particular culture. Lastly, some societies continue to find difficulty in facilitating open acknowledgment of the existence of child maltreatment in general and sexual abuse in particular.

Socioeconomic status is unrelated to the incidence of CSA in population studies (Berliner & Elliott, 1996) but there is an overrepresentation of lower socioeconomic groups in clinic samples (Bentovim *et al.*, 1987). This may be because these groups are more likely to come to the attention of child protective agencies than middle class families who may find ways of hiding the abuse or avoiding its reporting (Gomes-Schwartz *et al.*, 1990). Different forms of child abuse and neglect are not infrequently found in the same family and the same child (Mullen *et al.*, 1994), especially among the socially disadvantaged. CSA is associated with troubled family life including family disruption (Russell, 1986), reconstituted families, intrafamilial violence (Bifulco *et al.*, 1991), and parents who are perceived as emotionally distant and uncaring (Alexander & Lupfer, 1987).

Risk and maintaining factors for child sexual abuse

There is no unitary theory of causation to explain CSA. Although, by definition, it is an interaction between the abuser/perpetrator and child/victim, intention and responsibility rest with the abuser. The abuser's wish for sexual gratification and for power are the two main motivators. Pedophilia is based on sexual arousal to prepubertal children. An explanatory theory needs to include biological, psychological, cultural, and situational factors (Ward & Siegert, 2002).

Finkelhor's (1984) systemic model of four preconditions continues to provide a basis for understanding CSA. They are:

1 Motivation to sexually abuse children

Motivations include pedophilia, fear/avoidance of peer intimate and sexual relationships, sadism; interpersonal motivators such as a need to overpower or gain mastery over more vulnerable persons, often as a result of one's own past abuse and low self-esteem. Sexual interest in children and a consequent predisposition to sexual abuse is far commoner than the action, requiring other factors to exist before abuse will actually occur. Mothers who sexually abuse have been described as simultaneously attacking and emotionally engulfing or possessing their children (Welldon, 1988).

2 Absence of internal inhibitors

Absence of internal inhibitors includes the effects of alcohol and emotional dysregulation. Abusers also use cognitive distortions or rationalizations including minimization of the harm to the child; conceptualizing the abuse as "love" or "education"; and placing responsibility on the child or adolescent who is described as inviting or requesting the abuse.

3 Absence of external inhibitors

External inhibitors of sexual abuse include cultural, social, and family protective structures and relationships surrounding the child, in particular a secure attachment to primary caregiver(s), good monitoring of the child's whereabouts and the existence of confiding relationships for the child. Their absence renders the child or adolescent vulnerable to sexual abuse.

4 Child's vulnerability

The particular child's vulnerability by virtue of age, disability, neglect, being orphaned and homeless, social isolation, and previous sexual abuse all increase the likelihood of sexual abuse, all of which abusers recognize.

This explanatory schema does not remove the abuser's responsibility for the abuse, whatever the nature of contributory risk factors.

Maintaining factors

Despite a growing recognition of CSA worldwide, the censure surrounding it leads to secrecy, denial, and disbelief of children about its occurrence. About 1 in 3 young people show no outward indicators (Kendall-Tackett *et al.*, 1993), allowing abuse to be undetected over prolonged periods. This is particularly likely

with children as compared with adolescents (McLeer *et al.*, 1998). By the time sexual abuse is discovered in childhood, it has often occurred repeatedly. In the Radford *et al.* (2011) study, in 34% of cases of sexual assault by an adult and 82.7% of cases of sexual assault by a peer nobody else knew about it at the time of the interview. Children's own coping through a psychological accommodation process may help to maintain the secret.

Effects of child sexual abuse

Charting the "natural history" of sexual abuse-related symptomatology is difficult for a number of reasons. Most studies have been retrospective and have variously included clinical, convenience, and population samples. While there is no post CSA syndrome (Kendall-Tackett *et al.*, 1993; Paolucci *et al.*, 2001), CSA is a significant risk factor for mental health disorders both in childhood and adulthood (Cutajar *et al.*, 2010) as well as having effects on physical health. There has been little systematic study of the effects of CSA on people with learning disability. Findings suggest that the effects are similar to those in the general population (Sequeira & Hollins, 2003).

Effects in childhood and adolescence

Not all children who have been sexually abused will develop difficulties and some will develop them only later (Saywitz *et al.*, 2000). However, a wide range of difficulties, which may not appear immediately, has been found with considerable effect sizes: depression, anxiety, PTSD, self-harm, low self-esteem, conduct disorder, drug misuse, age-inappropriate sexual activity (Friedrich, 1993) and promiscuity, sexual victimization of other children, and academic underachievement (Kendall-Tackett *et al.*, 1993; Paolucci *et al.*, 2001; Cutajar *et al.*, 2010). Some symptoms – post-traumatic phenomena and sexualized behavior, attenuate only slowly (Beitchman *et al.*, 1991) even with treatment (Lanktree & Briere, 1995). Bulimia has also been found following CSA (Carter *et al.*, 2006). Sexual abuse may lead to unwanted pregnancy or sexually transmitted disease including HIV. Rarely, it may cause genital injuries. However, the search for conclusive evidence of CSA on the basis of physical signs is now deemed of limited value (Adams, 2010).

Useful instruments to assess effects include Children's Impact of Traumatic Events Scale – Revised (CITES-R) (Wolfe *et al.*, 1991) and the Trauma Symptom Checklist for Children (Briere *et al.*, 2001).

Factors and postulated explanations for variability

Paolucci *et al.* (2001) found that gender, socioeconomic status, type of abuse, age when abused, relationship to perpetrator, and number of incidents of abuse did not moderate the effects of CSA on depression, PTSD, self-harm, inappropriate sexual activity, and academic achievement. Cutajar *et al.* (2010) found that affective, anxiety, conduct, and other childhood Axis I disorders and drug abuse, but not PTSD, were significantly

associated with sexual abuse at a younger age. Penetrative abuse and abuse by more than one perpetrator were associated with mental health disorders.

The variability of post-sexual abuse difficulties, and the search for possible protective or ameliorating factors, has led to much research on moderating factors, with conflicting results, summarized in Yancey *et al.* 2013. They have grouped potential factors into (i) child's personal factors (age at abuse, gender, and attributions about the abuse); (ii) family factors (parental own sexual abuse and mental health and family stress); and (iii) abuse-specific factors (victim-perpetrator relationship and abuse duration and severity). Using a cluster analysis, they established four distinct subtypes of clinical presentation following CSA: (a) a highly distressed group with clinical levels of child-reported depression, anxiety and PTSD symptoms, and parent-reported internalizing, externalizing, and sexualized behaviors; (b) a problem behavior group with parent-reported difficulties as in (a); (c) a self-reported distress group of children reporting difficulties as in (a); (d) a subclinical group with low level child and parent reports, respectively. They found that (i) a child's negative attributions about the abuse such as self-blame and shame correlated significantly with being in the highly distressed and problem behaviors groups; (ii) children in the highly distressed group had parents with depression; (iii) children whose sexual abuse included penetration were more often in the highly distressed group.

Other influences on outcomes have been found. Maternal coping through avoidance strategies correlates with deterioration in behavior (Oates *et al.*, 1994). Onset of sexual abuse before the age of 7, appears to be a risk factor for later inappropriate sexualized behavior (McClellan *et al.*, 1996; Mian *et al.*, 1996). Boys experience anxiety about their own latent homosexuality or having been rendered homosexual by the abuse (Watkins & Bentovim, 1992). Distress following CSA is greater in girls with higher cognitive functioning (Shapiro *et al.*, 1992). Interestingly, the child's coping strategies and cognitive evaluation of the abusive experiences have been shown to contribute less to the child's later functioning than severity of the abuse and the support of the non-abusing caregiver (Spaccarelli & Kim, 1995). Bal *et al.* (2003) suggest that for adolescents, avoidant coping strategies following sexual abuse are associated with more distress.

Protective factors

The non-abusing parent(s)' belief, support, and active protection of the child are significant determinants of a better outcome for the child regardless of the nature of the sexual abuse (e.g., Everson *et al.*, 1989). Conversely, the closer the relationship between the abuser and the non-abusing caregiver(s), the less the child will be supported by her caregiver(s) (Berliner & Elliott, 1996).

Effects in adulthood

Mental health

CSA is followed by significant adult mental health problems (Fergusson *et al.*, 1996) and has been estimated to contribute

independently to 13.1% of adult psychopathology (Fergusson *et al.*, 2008). Findings from many retrospective studies have been confirmed by a large, controlled prospective study from Australia (Cutajar *et al.*, 2010), which found that 23.3% (22.5% female, 26.5% male) of adult survivors of substantiated CSA required lifetime (childhood or adulthood) mental health services, in comparison with 7.7% of a comparison population sample. Effects are summarized in the Table 30.4.

Stigma and self-blame, but not betrayal and powerlessness, have been found to mediate the effects of sexual abuse on adult psychological functioning (Coffey *et al.*, 1996). Contrary to common belief, a systematic review of the impact of CSA on health (Maniglio, 2009) did not find that a number of variables concerning aspects of the abuse experience, such as age when abused, incestuous abuse, level of contact, use of force, frequency, and duration of abuse, influence the outcomes of CSA.

Only a minority of homosexual men have been sexually abused in childhood, and they have no greater sexual interest in children than heterosexual men.

Physical health

CSA, among other forms of maltreatment and other adverse childhood experiences, is significantly associated with adult physical illnesses and earlier death (Felitti *et al.*, 1998).

Neurobiological effects

There has been a burgeoning of empirical findings regarding neurobiological effects of childhood stressors and maltreatment, including CSA. These findings describe, and to some extent, explain the observed and reported effects following CSA (for details, see Chapter 29).

Suspicion, recognition, investigation, validation, and protection

Principles

Whenever sexual abuse is suspected or presented explicitly to a professional, including child mental health practitioners, a multi-agency professional involvement will follow. Its broad aims are to ascertain what, if anything, has happened to the child and to gain an understanding of the child's current functioning, family context, and needs. If the child has been abused, the child's needs will include:

- (a) immediate and long-term protection
- (b) amelioration of the effects of the abuse including
 - (i) reduction of distress and the resolution of internal conflicts and mental health disorders
 - (ii) resolution of interpersonal conflicts surrounding the child
 - (iii) treating physical consequences of the abuse
- (c) ensuring optimal development for the child following cessation of abuse.

The achievement of these aims is, in practice, fraught with difficulties. Suspicions need to be verified and a child's account tested, because protection comes at a cost and therapy can only follow protection. As there are rarely witnesses to the abuse, establishing whether it has occurred will rest heavily on the child's verbal description, which may be retracted even if it was true. Discovery of abuse is often accompanied by denial by the alleged abuser, and some doubt or disbelief, and usually constitutes a crisis for the family and a challenge to the professional system. The child's ultimate well-being will, to a significant extent, be determined by the support given by the family. The nature of the early intervention by professionals, and their consideration of the position and needs of the mother or non-abusing caregivers, will have long-lasting effects on the child's and the family's subsequent expectations and attitudes toward professionals with whom they may need to continue to work.

In most countries, the responsibility for protecting the child rests with social services or the courts to whom suspicions of, or actual abuse are reported. The subsequent multidisciplinary and multi-agency process involves, in addition, the police, health, education, and the courts. A number of well established, coordinated steps in the process have been identified, each step depending on the outcome of the previous one, and involving a number of agencies:

- 1 Suspicion or recognition leading to referral to (child protection) social services
- 2 Establishing whether there is a need for immediate protection
- 3 Planning the investigation including
 - interagency discussion
 - interviewing the child
 - medical examination of the child
 - initial assessment of the family
- 4 Validation and initial child protection meeting (conference) leading to a protection plan and a more comprehensive assessment
- 5 Implementation of plans and review
- 6 Possible criminal prosecution
- 7 Therapy.

Suspicion, recognition, and disclosure

CSA either comes to light when a child talks about it to a friend, relative, or a teacher or is suspected on the basis of one or more indicators which are more or less specific. Spontaneous and intentional disclosures are likely to be credible. Specific indicators include: age-inappropriate sexualized behavior, and rarer genital physical signs, sexually transmitted diseases, and pregnancy in a young girl or when the identity of the father is unclear (NICE, 2009). Nonspecific indicators include sudden onset of unexplained difficulties in a previously untroubled child such as distractibility, educational deterioration, social isolation, aggressiveness, low self-esteem, marked unhappiness, disturbed sleep and nightmares, fearfulness, and separation

Table 30.4 Adulthood effects of CSA.

Studies	Gender effects	Effect	Precursors and explanations
Cutajar <i>et al.</i> (2010)	Women = men Men > women	Anxiety, Drug misuse Antisocial personality disorder	
Cutajar <i>et al.</i> (2010), Morgan and Fisher (2007), and Read <i>et al.</i> (2005)	Women > men	PTSD, depression, alcohol misuse, borderline personality disorder, schizophrenia	CSA in adolescence, penetrative abuse, >1 perpetrator
Mullen <i>et al.</i> (1994)	Women	Suicidal behavior, difficulties in sexual functioning & intimate interpersonal relationships, low self-esteem, unskilled or semi-skilled work	
Kendler <i>et al.</i> (2000)		Major depression, anxiety, drug & alcohol misuse	Not confounded by genetic factors or mediated by common environmental factors

anxiety. Depression, running away, deliberate self-harm, and drug and alcohol misuse may arise later.

CSA of other children in the family and known contact with a sexual abuser should also raise the possibility of abuse of a particular child.

Source and explanations for indicators of CSA need to be explored in a non-leading way. This is important as children (especially younger ones) will not usually describe sexual abuse during a formal interview, unless they have previously spoken about it (Keary & Fitzpatrick, 1994). (The converse is not, however, true). As a result of such enquiries, sexual abuse may come to light.

Disclosure of sexual abuse needs to be reported to social services or police who will inform each other; confidentiality will need to be overridden. A child may not wish for their disclosure to be passed on. As this cannot be honored, the child's misgivings need to be explored, and the child requires an explanation for the need to report the abuse. Referral is usually made with the knowledge of the family, unless there are indicators that this will place the child at increased risk which includes placing pressure on the child to retract an allegation.

The investigation, protection, and formal interview

The need for immediate protection is a decision of social services or the court in consultation with other professionals and agencies. There are helpful guidelines in most developed countries, including those by the American Academy of Child and Adolescent Psychiatry on evaluation and treatment of trauma abuse (AACAP, 1997).

Children will be interviewed formally if there are clear suspicions of abuse or if the child has already disclosed the abuse informally. The formal interview should be carried out by trained professionals, usually police and social workers, and video-recorded evidence can be used both for criminal prosecution and/or civil legal child protection proceedings. It is therefore carried out according to strictly specified guidelines

(Lamb *et al.*, 2007). Rarely, when children are too distressed or traumatized or have significant difficulties in communication, a child mental health professional may be required to interview the child. Facilitated Communication with autistic children who are suspected of having been abused is not recommended (Howlin & Jones, 1996). Anatomically-correct dolls should not be used as a screening tool or cue despite little evidence that young, non-abused children proceed beyond exploration of the dolls' genitalia (Glaser & Collins, 1989).

Validation

Validation of CSA requires assessment of the evolution of suspicions and the circumstances as well as the crucially important content of the child's first description or disclosure of abuse; the outcome of a formal interview; findings in a medical examination; family circumstances; the child's relationship with the alleged abuser; and the responses to the allegation by the mother or the non-abusing caregivers and by the alleged abuser. In a retrospective review of 551 case notes of reported concerns about possible CSA, 43% were substantiated, 21% were inconclusive, and 34% were not considered to be abuse cases. Only 2.5% were erroneous concerns emanating from children, and included only 8 (1.5%) of false allegations originating from the child, and 3 made in collusion with a parent (Oates *et al.*, 2000). In other studies, false allegations are found to be most commonly made by a parent in the context of contact or residence disputes between warring parents, or rarely under the influence of a parent in the context of inter-parental disputes (Faller, 2005).

The nature of protection

A child can only be protected from further harm when all contact with the alleged abuser is either fully supervised or stopped and when the child is believed and not blamed for the abuse or the disclosure. Children abused by persons outside the family tend to be excluded from child protective services on the, sometimes erroneous (Tebbutt *et al.*, 1997), assumption that they will be protected by their families. If protection is achieved, and if no

legal proceedings ensue, there may never be a formal record of the validated fact of the abuse.

Legal proceedings

In cases of alleged CSA, both civil family and criminal proceedings may be involved in parallel and often independently. Civil proceedings concern the future safety of the child within which the child's welfare is usually paramount and hearsay and expert evidence are allowed. Civil proceedings determine whether the child has been harmed and how the child's well-being is to be ensured in future. Criminal proceedings are concerned with determining the guilt or innocence of the alleged abuser and the child is a mere accessory or witness whose testimony will be heavily scrutinized. In some jurisdictions, the child's account, previously video-recorded in the formal interview, can be produced but the child will still be cross-examined, preferably through a video link. Expert opinion regarding the child's credibility is not permitted in English criminal courts, that being an issue for the jury and the judge to decide.

In some jurisdictions, protection of the child by social services, on the basis of civil law, relies on the outcome of a prior criminal trial. If there is no prosecution or no conviction, the child will remain unprotected.

Therapeutic work, which can only meaningfully commence after protection, may need to be postponed until the child's evidence has been heard in a criminal trial.

Therapeutic work

Therapeutic work follows closely on protection. A systemic treatment approach to the effects of CSA attends to the child's needs both individually and in the context of the family. Relationships between the three participants in the "abuse triangle" – the abuser, the child, and the non-abusive caregiver(s) (Glaser, 1991) are important. Some of the child's acute difficulties may be related more to their family's response to the abuse or to moves and separation from the family than to the sexual abuse. Work with the child needs to be linked with work with the parent(s) or caregivers and family, separately and together.

Fulfilment of children's therapeutic needs

Not all children who have been sexually abused require therapy. However, a minimum requirement is for the child to have an appropriate narrative about their abuse and to have access to an identified person who believes the child and is able to listen to the child supportively and uncritically. Coping by avoidance, which includes not being able to talk about the abuse when appropriate, is a predisposing factor for the development of PTSD (Kaplow *et al.*, 2005). Children who have been sexually abused also require age-appropriate education about sexuality and the nature and risks of sexual abuse.

Although some symptoms such as sexualized behavior are readily apparent, others such as PTSD or depression may need

to be actively sought within a full assessment of the child's functioning. It is important to include children who have been abused by strangers or by someone outside the family (Grosz *et al.*, 2000), as their therapeutic needs may be overlooked when protection from re-abuse is not required.

There are several ways in which treatment approaches for children can be categorized. Children may be treated individually or in groups; treatment may be offered to a sexually abused child or directed at specific symptoms; there is a range of different treatments including psycho-education about sexual abuse, sexuality and self-protection, comprehensive brief trauma-focused work with the child and parents, and intensive and more prolonged therapeutic work. Finkelhor & Berliner (1995) found that overall, therapy facilitated recovery independently of time elapsed from the abuse and other external factors and particularly when directed at specific difficulties. Others have found no effects of treatment (Oates *et al.*, 1994; Tebbutt *et al.*, 1997) or some deterioration during therapy for a minority of children (Jones & Ramchandani, 1999). It is not clear what contribution intercurrent developments in the child's life or therapy made to the reported deterioration. Despite this, treatment should be offered to symptomatic children.

Several meta-analyses have found large to moderate effect sizes for psychotherapy, group treatment, and CBT combined with supportive, psychodynamic, or play therapy. King *et al.* (2000) found that, compared with wait-list controls, children with PTSD who received CBT either individually or as a family intervention improved equally in both treatment conditions.

Group therapy

Overall good outcomes have been reported for group therapy in terms of general psychological distress, internalizing and externalizing symptoms, sexual behaviors, self-esteem, and knowledge of sexual abuse/prevention (Reeker *et al.*, 1997). Several reviews have shown individual and group treatments to be equally effective (Trask *et al.*, 2011).

Parallel groups for caregivers support the process (Rushton & Miles, 2000).

Individual therapy

Several meta-analyses (Hetzel-Riggin *et al.*, 2007; Sánchez-Meca *et al.*, 2011; Trask *et al.*, 2011) have found an overall improvement in the many difficulties studied. Longer duration of treatment was associated with larger effect sizes and treatment effects tended to be maintained. There were conflicting results regarding the inclusion of the caregiver. Boys did well.

Specifically, several studies of trauma-focused cognitive behavioral therapy (TF-CBT) (Cohen *et al.*, 2006) were included in the meta-analyses. This programmatic, trauma-focused work involves the child and parent. It includes psycho-education, parenting skills, and relaxation for the child; recognition of feelings and learning to master and modulate affect are followed by cognitive coping. A narrative account is followed by beginning of reprocessing of the traumatic experience,

correcting inaccurate recollections and unhelpful cognitions and mastering traumatic reminders. Despite some uncertainty regarding the outcomes (Macdonald *et al.*, 2012), it is likely that TF-CBT is helpful for PTSD, anxiety, and depressive symptoms but may be less effective in treating externalizing behaviors. Nondirective supportive therapy does not appear to be of much benefit. Adolescent depression following sexual abuse appears to respond less well to CBT (Barbe *et al.*, 2004).

Therapeutic work with caregivers and family

Non-abusing caregivers

The outcome for the abused child is, in part, determined by the mental health of the non-abusing caregivers, who are often faced with a conflict of loyalties between the abuser and the child, as well as guilt for not protecting the child and possibly memories of their own past abuse. Lack of belief in and support of the child may lead to removal of the child. Individual or group work is therefore important.

Siblings and the family

Siblings are sometimes the silent witnesses of abuse and may be overlooked. Whole family meetings are important in enabling the family to talk openly about the fact of the abuse but would not include an abuser unless he has taken responsibility for the abuse and is receiving treatment. Other dysfunctional aspects of family interactions that are associated with CSA include, in particular, inappropriate intergenerational boundaries, and parental neglect and unavailability which also need to be addressed (Elton, 1988).

Work with abusers

Child and adolescent abusers

The treatment of child and adolescent abusers requires coordinated support by child protective and youth justice systems as well as support by the young person's parents or primary caregivers. Cognitive behavioral therapy (Kolko *et al.*, 2004) which may be offered individually or in groups, includes:

- challenging denial and minimization of the abuse and responsibility for it
- sex education
- development of social skills
- victim awareness
- recognition of cognitive distortions concerning the abuse
- mapping the abuse cycle (Hawkes, 1999) and learning to halt its progression.

Structured group work for children and young adolescents who had sexually abused has been shown to be effective with a long follow-up showing little recurrence (Carpentier *et al.*, 2006).

A small number of children and adolescents may show features of lack of empathy and cruelty, which will indicate a more serious problem and call for careful monitoring of the child and very skilled therapy, sometimes requiring residential care (Vizard *et al.*, 1995).

Adult abusers

Treatment for adult abuser is important for those children who wish to resume a meaningful relationship with him and for society in general. Therapy addresses denial of the extent of the abuse, responsibility for the abuse, and the harm caused to the child. CBT has shown significant reduction in recidivism in sex offenders (Hanson *et al.*, 2002).

Conclusions

CSA is a definable and often repeated event that is embedded in a complex web of contextual factors, both historical and relational. Its antecedents and consequences are manifold and not necessarily specific. For these reasons, specific prevention is particularly difficult and alertness to the possibility and early recognition offer the best hope for damage limitation. Children cannot be relied upon to protect themselves. Secrecy, denial, and disbelief are integrally related to sexual abuse and exert a very significant influence on the professional response and outcome for the children and their families.

CHAPTER 31

Brain disorders and psychopathology

Isobel Heyman^{1,2}, David Skuse² and Robert Goodman³

¹Psychological Medicine, Great Ormond Street Hospital for Children, London, UK

²Institute of Child Health, UCL School of Life and Medical Sciences, University College London, UK

³Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

This chapter focuses on the psychiatric features of childhood brain disorders, including epilepsy. This topic has variously been called “organic child psychiatry,” “pediatric behavioral neurology,” and “developmental neuropsychiatry.” The terms “functional” and “organic” have previously been used to differentiate between idiopathic mental illness, where no neurological basis for the disorder could be found, and conditions in which there was clear evidence of neural dysfunction. The terms used to make the distinction are now rarely employed. A wide range of evidence shows that there is often a neural substrate for neurodevelopmental disorders that were at one time regarded as being “functional” in origin, including autism (see Chapter 51), schizophrenia (see Chapter 57) and ADHD (see Chapter 55) (Steen *et al.*, 2006; Amaral *et al.*, 2008; Rapoport *et al.*, 2012; Arnsten & Rubia, 2012; Lai *et al.*, 2013). For many clinicians and researchers in child mental health, the claim that persistent abnormalities in behavior and emotion often have an underlying neural basis is neither surprising nor controversial. Therefore, to make a distinction between disorders of “brain” and “mind” could be regarded as misleading or even meaningless. Cognizant as we are of this potential criticism, we are discussing in this chapter conditions where there is a relatively direct link between neurological disorder and psychopathology, with a focus on epilepsy and cerebral palsy.

In trying to understand the relationships between disorders of brain and their impact upon specific psychopathologies, we need to draw on knowledge from both child psychiatry and child neurology. Unfortunately, relatively little is known about how best to classify such conditions based on their etiology, course and management, from the perspective of psychiatry or neurology. For that reason, making firm statements about the relationship to be anticipated between disorders of brain and behavioral problems in childhood is unwise. The task is made all the more difficult because of changing classification rules for both psychiatric disorders and neurological

conditions such as epilepsy. These difficulties are not mentioned to discourage readers, but to put them on their guard against expecting a summary that draws simplistic conclusions from inadequate data.

Brain damage?

This chapter is deliberately entitled “Brain Disorders and Psychopathology” rather than “Brain Damage and Psychopathology.” The term “damage” suggests that the brain was developing normally until something happened to damage it. While this description accurately portrays a pathological process in a few conditions, such as athetoid cerebral palsy (which can follow rhesus hemolytic disease), hydrocephalus that may arise from the consequences of tuberculous meningitis and epilepsy following a penetrating head injury, it is more usual for neural development to have been following an abnormal developmental path from embryonic life. The neural anomalies that are associated with child psychopathology usually have a genetic substrate, although their developmental trajectories are shaped in part by environmental conditions encountered both in utero and beyond. Such anomalies include novel genetic mutations as well as structural chromosomal aberrations (Cooper *et al.*, 2011). As far as the common brain disorders in childhood are concerned, we do not know if acquired or intrinsic etiologies are more important. Sometimes, children with cerebral palsy or (intellectual disability) ID (formerly called “mental retardation”) are labeled as “brain damaged”; parents and researchers therefore tend to assume that the cause must be some insult, such as a difficult birth. In such cases, the role of genetically or chromosomally determined malformations tends to be overlooked. The term “brain damage” is, however, capable of wide interpretation, and some have used it to include the impact of persistent inflammation or even epigenetic changes (Fleiss & Gressens, 2012).

A disadvantage of the term “brain damage” is that it suggests permanence to anyone who has been taught that the brain cannot regenerate lost or damaged parts. This connotation of irreversibility is potentially misleading. Take the example of epilepsy. Children do commonly “grow out of” epilepsy. Reversible “organic” brain disorders of this type may arise not from fixed abnormalities of neuronal organization but from delayed or precocious neuronal maturation. It is plausible (although currently unproven) that transient childhood epilepsy reflects temporarily delayed development of inhibitory neurotransmitter systems (or prematurely accelerated development of excitatory systems). We are also learning more about the structure of the brain in normal and abnormal development and the relationship between structure and psychopathology (Giedd & Rapoport, 2010; Shaw *et al.*, 2010). On the other hand, although there are, in broad terms, different developmental brain trajectories in disorders such as autism, schizophrenia and ADHD, the science is still not at a level where we can interpret an individual scan and find it informs us about the psychopathology of an individual child. Some authors believe that evidence that brain imaging can guide diagnosis or treatment in conditions such as developmental language disorders has not been forthcoming, and also that imaging has not significantly advanced our understanding of brain and behavior relationships (Bishop, 2013).

Birth damage

The best-known “brain damage” theories are those that propose that trauma at birth is a frequent cause of later developmental disorders with neurological correlates. Generations of medical students have been taught that cerebral palsy, epilepsy, and severe intellectual disabilities are commonly caused by brain abnormalities arising from perinatal complications. This view is almost certainly false.

Obstetric and neonatal complications are common but are generally innocuous. Even severe perinatal complications are usually harmless. Most children who experience birth asphyxia do not develop cerebral palsy. Conversely, even the approximately 20% of children with cerebral palsy who do have a history of birth asphyxia, have been subject to other risk factors that antedated birth. They are found to possess, for example, congenital malformations or microcephaly at birth; the fetuses were already abnormal before labor began (Bilder *et al.*, 2013), therefore the birth process could be regarded as a “harmless marker.”

The fetus is an active participant in the delivery process, not simply a passive passenger who is expelled when his or her time is up. Accordingly, it is not surprising that a genetically abnormal fetus has an enhanced liability to an abnormal birth (Bilder *et al.*, 2013), although it is possible that perinatal complications compound anomalies that have already occurred prenatally. The “harmless marker” hypothesis is supported by findings

that cerebral palsy rates in children born at term have been fairly steady in recent years, despite major advances in perinatal management and a dramatic fall in perinatal mortality (Paneth *et al.*, 2006). If perinatal complications commonly converted normal or vulnerable fetuses into cerebral palsied children, improvements in obstetrics and neonatal pediatrics should have resulted in a clear fall in the rate of cerebral palsy, but this does not appear to have occurred. More recent work has suggested that some single-gene disorders can lead to cerebral palsy, although this is controversial (O’Callaghan *et al.*, 2012) and it is likely that, as in other neurodevelopmental conditions, many cases are caused by multiple gene effects (Moreno-De-Luca *et al.*, 2013).

Although this account has focused on the extent to which birth complications are largely irrelevant to cerebral palsy (probably accounting for fewer than 10% of cases), similar considerations may apply to severe intellectual disabilities. There is a higher rate of perinatal complications in children whose severe ID is genetic or chromosomal in origin. Intellectual disabilities can be caused by environmental and/or genetic factors, although in 60% of cases no identifiable cause can be found (Rauch *et al.*, 2012). Increasing evidence indicates that genetic influences are causal in a substantial minority of cases, and the proportion is rising (Kaufman *et al.*, 2010). For epilepsy too, prenatal risk factors appear far more important than perinatal risk factors (Wallace, 2004).

In some circumstances, complications arising from birth can cause brain damage that results in behavioral and cognitive problems in later life, even in the absence of neurological signs (Moore *et al.*, 2012). Substantial research has shown that children born very prematurely, especially those born before 30 weeks gestation, are at high risk. Follow-up studies of children born weighing less than 1500 g show that, even when those with overt neurological disorders are excluded, there is a consistently higher rate of attention-deficit hyperactivity disorder (ADHD). Rather less evidence has been adduced for an increase in the rate of conduct or emotional disorders (Johnson, 2007). Studies using neonatal ultrasound scans have shown that the periventricular white matter damage that commonly occurs in children born before 28 weeks gestation (see Figure 31.1 Brain scan PVL) is strongly associated with subsequent cognitive and psychiatric problems, even when the children do not develop overt neurological disorders (Woodward *et al.*, 2012). White matter damage in very prematurely born children results in cerebral palsy and is associated with an especially high risk of comorbid psychiatric problems (Elgen *et al.*, 2012).

Brain dysfunction increases the risk of child psychiatric disorders

The neuropsychiatric component of the classical Isle of Wight epidemiological study showed that brain disorders were powerful risk factors for psychiatric disorders. Among children with

Figure 31.1 Axial T2W MRI brain scan demonstrates marked periventricular white matter injury in an ex-premature baby. There is lateral ventricular dilatation secondary to white matter volume loss in keeping with Periventricular Leukomalacia (PVL).

structural brain anomalies (evidenced by neurological signs rather than by neuroimaging), the rates of psychiatric disorders were 44% compared with 29% among children with idiopathic epilepsy and just 12% among children with non-cerebral physical disorders (such as diabetes). The equivalent figure was 7% among children free from physical disorders (Rutter *et al.*, 1970). Almost 30 years later, the British Child and Adolescent Mental Health Survey reported strikingly similar results (Davies *et al.*, 2003). The finding that cerebral disorders conferred a much higher psychiatric risk than non-cerebral disorders strongly suggested the existence of direct brain-behavior links. Many other studies have since confirmed that psychiatric problems are more likely to result from brain disorders than from physical disorders that do not involve the brain (e.g., Howe *et al.*, 1993; Baca *et al.*, 2011).

At risk for which psychiatric disorders?

There is a long running controversy about the extent to which brain disorders are risk factors for particular sorts of psychiatric problems, as opposed to non-specific risk factors for all types of psychiatric problems. The truth lies between these two extremes: brain disorders increase the risk of most psychiatric problems, but not to the same extent. For example, ADHD (then known as Hyperkinetic Disorder) was exceptionally over-represented among children with cerebral palsy or epilepsy on the Isle of Wight (Rutter *et al.*, 1970). A more recent UK epidemiological study showed that autism is relatively common among children with epilepsy (Davies *et al.*, 2003). There is specificity

between certain neurological disorders and the type of psychiatric disorder associated with them. The risk of autism is increased in cases of tuberous sclerosis (Tsai & Sahin, 2011); Pediatric Autoimmune Neuropsychiatric Disorders (PANDAS) are associated with streptococcal infections, and include tic-like conditions as well as obsessive-compulsive disorder (Snider & Swedo, 2004). When the neurological disorder has a genetic basis, as in the case of tuberous sclerosis (Figure 31.2 Brain scan TS), the associated psychiatric problems comprise a “behavioral phenotype” of the underlying genetic disorder. Behavioral phenotypes are not specific to a disorder; there is a considerable overlap between symptoms associated with a wide range of genetic risks, but statistically significant associations do exist (see www.ssbp.org.uk which provides information sheets on many genetic syndromes).

How do neurological and non neurological risk factors interact?

As described in the rest of this volume, a multitude of psychosocial and genetic factors influence a child’s liability to psychiatric disorders. How do these “ordinary” risk factors interact with neurological risk factors? First, children with brain disorders are also subject to common environmental risk factors and these may interact with the underlying biological vulnerability. In the Isle of Wight study, children with evidence of structural brain anomalies were exceptionally likely to have a psychiatric problem if they also came from a “broken home” or had an emotionally disturbed mother (Rutter *et al.*, 1970). A plausible

Figure 31.2 Axial FLAIR MRI in a two year old demonstrate typical findings of tuberous sclerosis: Several cortical/subcortical tubers (black arrows), “white matter radial migration lines” (open arrow) associated with “subependymal nodules” (white arrow) are demonstrated.

explanation is that neurologically determined behavioral problems had been responsible for an adverse impact on the parents' marriage and on the parents' mental state. Cross-sectional studies cannot determine the direction of causation. In a longitudinal study that is designed to disentangle causal pathways, evidence may be found for a causal process. Consider the prospective study of childhood head injury carried out by Rutter *et al.* (1984). Although the severity of head injury was the most powerful single predictor of whether a child would develop a psychiatric problem, ordinary risk factors for disorders (such as psychosocial adversity) were also influential. Among children with severe head injuries, new psychiatric disorders developed in 60% of those who prior to the injury had experienced high levels, but in just 14% of the children who had experienced low levels of psychosocial adversity.

Occasionally, the impact of neurological impairment may confer such substantially greater risk for child psychiatric problems that prosaic factors normally associated with risk no longer impact. For example, among prepubertal children without neurological problems, boys are at considerably greater psychiatric risk than girls, especially of behavioral or externalizing conditions (e.g., Rutter *et al.*, 1975). By contrast, several studies of children with neurological brain disorders have reported that psychiatric risk is not differentiated by sex. This lack of sexual dimorphism was reported in the Isle of Wight sample of children with brain disorders (Rutter *et al.*, 1970), and (Rutter

et al.'s 1984) study of children followed prospectively after a severe head injury.

Our current understanding of the interaction between neurological and environmental risk factors suggests two lessons for clinicians. First, children with brain disorders are as vulnerable as any other children to social and other environmental risk factors. Accordingly, the severity and frequency of psychiatric problems in this high-risk group could be reduced by non specific interventions, such as improving the quality of the care provided by parents. Interventions that are designed to reduce discord between parents and/or siblings, to provide consistency of supervision, and to increase the child's confidence through praise and shaping of prosocial behavior would all be beneficial. Secondly, for some children the “behavioral phenotype” may be exceptionally strongly influenced by the underlying neurological dysfunction. Vulnerability in these children to psychopathology is therefore relatively unaffected by psychosocial adversity. In cases with “strong” behavioral phenotypes, psychiatric problems will be found even in the most favorable of environments. Examples include the hyperphagia associated with Prader-Willi syndrome (McAllister *et al.*, 2011). Clinicians who bear this in mind should reassure parents, and teachers, who sometimes blame themselves for not having done enough to prevent the emergence of psychiatric problems. Families and schools who are doing a good-enough job with an extremely challenging group of children should feel admired rather than blamed.

What are the mediating links?

Why do children with “organic” brain disorders have relatively high rates of psychiatric problems? This question should be posed at the beginning rather than at the end of neuropsychiatric investigations. Uncovering the mechanisms that link brain disorder to behavioral dysfunction will shed light on the biological determinants of normal psychological development, as well as on prevention and treatment. Thus, practical implications of clarifying brain-behavior relationships are substantial. For example, in our clinical practice, we often encounter children with disorders of neural development in which there are severe, but unrecognized specific learning difficulties (see Chapter 52). Because the nature of the cognitive deficits are not obvious (and may be uncovered only by specialist testing) they go unrecognized. The child cannot keep up with his or her lessons and that engenders marked frustration with schooling, leading on to defiant and disruptive behavior in class. In other circumstances, the presence of an overt neurological problem might lead to psychiatric problems as a consequence of parental overprotectiveness, or from inconsistent discipline provided by a parent who is suffering guilt because they regard themselves to blame for the child’s neurological disorder. The capacity of even highly educated and intelligent parents to inflict blame on themselves (or on their child’s medical care), based on the most tenuous of presumed causal events, is remarkable and must be addressed by clinicians.

Unfortunately, because there is a dearth of relevant empirical studies, current accounts of mediating processes are based largely on clinical plausibility. It is worth reiterating that just because a child has both neurological and psychiatric symptoms, it does not necessarily follow that the former caused the latter: a child with cerebral palsy who is disrupting the class may be doing so because of school stresses that are unrelated to the child’s brain disorder. Alternatively, the two sets of problems may reflect a common origin. A child’s head injury and an associated conduct disorder may both be due to inadequate parental supervision. Alternatively, in some cases the psychiatric problem could have caused the neurological disorder. Children with ADHD may run impulsively into the road, get hit by a car, and suffer brain damage as a consequence. With these reservations, it is now appropriate to consider instances in which the child’s brain disorder will have played some direct or indirect part in the origin of the concomitant psychiatric problems. For the sake of clarity, it is helpful to distinguish between the organic and psychosocial consequences of a brain disorder (see Figure 31.3), acknowledging that these are often intimately interrelated.

An “organic” brain disorder may lead to developmental problems in physical, educational and neurobehavioral domains. If there are associated physical disabilities (ranging, for example, from easy fatigability to lack of independent mobility) these may have an indirect impact on psychological well-being. The child who is exhausted by everyday playground activities could suffer reduced self-esteem, compounded by their limited

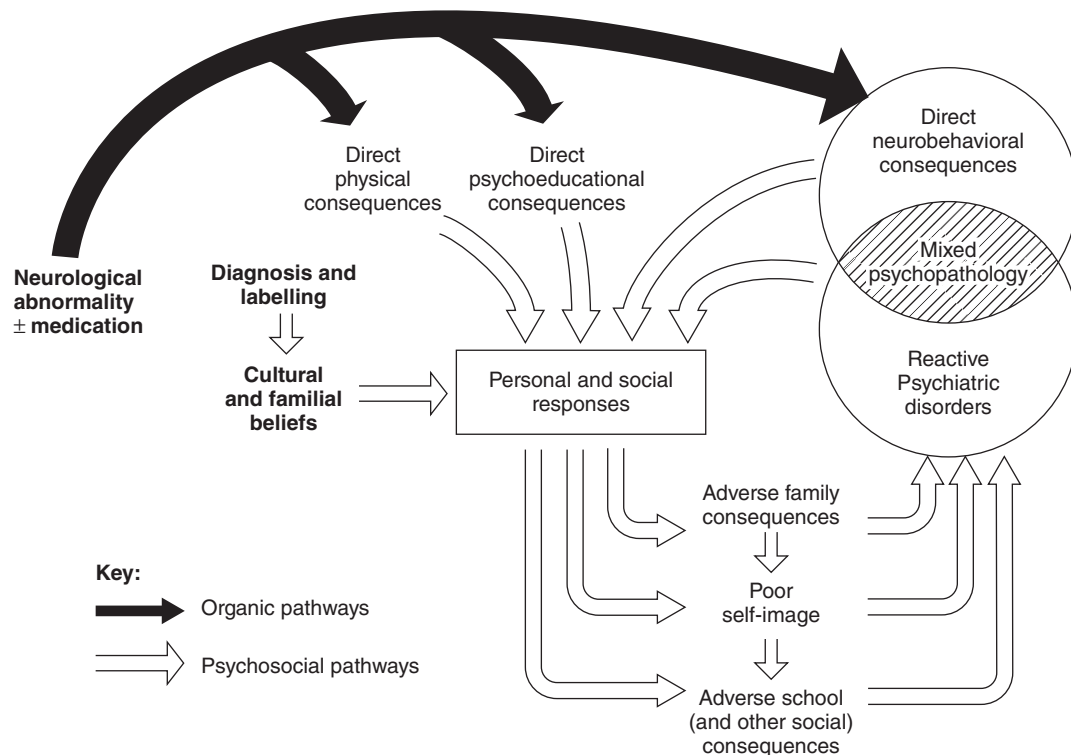

Figure 31.3 A simplified representation of organic and psychosocial pathways from brain to behavioral abnormalities.

opportunities to develop peer relationships. Treatment regimes for physical problems can be disruptive to the child's life. For instance, many hours each week could be spent in physiotherapy, during which the child is sacrificing time when they would prefer to have been playing. Reluctance to engage with treatment occasions "I don't want to do it" battles. In more serious cases of neurological impairment, children experience repeated hospital admissions, with attendant separations and an impact on family integrity.

Specific learning problems and below-average intelligence are common psycho-educational correlates of structural brain abnormalities (e.g., Rutter *et al.*, 1970; Reilly & Neville, 2011). There is often a direct link between the impact of the underlying brain disorder on neural functioning and impaired cognitive processing. On the other hand, risk is sometimes aggravated by restricted educational opportunities, lower expectations, and lengthy absences from school for therapy or operations. For children with epilepsy, their cognitive and scholastic skills can be disrupted not only by clinical and subclinical seizures, but also by the effects of antiepileptic medication.

The evidence that brain disorders arising from genetic risk lead directly to specific childhood psychopathology is largely circumstantial. Recent research with animal models for genetic risk is beginning to illuminate causal mechanisms (see Nestler & Hyman, 2010). Medical treatments, provided for neurological dysfunction, can also have an adverse impact on children's behavior. These include steroids, which affect activity and mood (Stuart *et al.*, 2005), and antiepileptic drugs (Bath & Scharfman, 2013). Thirdly, biologically mediated mechanisms can provide an adequate explanation for some specific neuropsychiatric associations in childhood, such as the association between Prader-Willi syndrome and characteristic sleep and appetite problems, or the association between Lesch-Nyhan syndrome and severe self-injury (see Chapter 24). In summary, brain disorders can have a multitude of psychosocial consequences. Physical disabilities can result in teasing, poor self-image and reduced opportunities for peer interaction. Repeated hospitalizations may disrupt friendships and predispose to behavioral disorders, perhaps as a result of repeated separations from family. Specific learning problems and low intelligence are also associated with a much higher rate of psychiatric problems in children with brain disorders, just as they are in ordinary children (Rutter *et al.*, 1970; Ryland *et al.*, 2010). Many organic brain disorders also have neurobehavioral consequences, especially poor attention, hyperactivity and an impaired ability to decipher social and emotional cues. While these consequences are relatively non-specific, they may, in turn, have adverse effects on family relationships as well as the ability to make and sustain friendships at school and elsewhere outside the home.

The beliefs and attitudes of the family and the wider social world also have a major impact on emotions and behavior in the child. Parents, teachers and peers respond to a neurologically impaired child in the light of their beliefs and prejudices about "brain damaged" children. These beliefs influence the likelihood

of overprotection, peer rejection and unrealistic expectations. Unhelpful attitudes about the nature of their child's condition can interfere with parents' abilities to set limits to unacceptable behaviors. Some parents assume that all bad behavior is driven by the neurological abnormality and that it is therefore beyond the child's control. Others fear that any reproof will trigger an epileptic seizure and further damage the child's brain. Family relationships can be disrupted for other reasons as well. Sibling rivalry, for example, can be fuelled by the resentment of disabled children who see themselves being overtaken by younger siblings, or by the resentment of non-disabled siblings who feel they are missing out on parental attention. These are only a few of the many possible psychosocial pathways from brain disorders to child psychiatric problems. In a recent study of children with epilepsy, factors that most compromised quality of life included impaired cognitive ability and disrupted family functioning (Speechley *et al.*, 2012).

Longitudinal studies provide a valuable research strategy for investigating the causal mechanisms underlying cross-sectional associations. A longitudinal study of children with hemiplegic cerebral palsy found that adverse family factors, including low parental warmth or marital discord, were more likely to be consequences than causes of the child's psychiatric problems (Goodman, 1998). Thus adverse family circumstances at baseline did not independently predict whether the hemiplegic child improved or deteriorated by the time of follow-up. Intervention studies could also be powerful research strategies for investigating the causal mechanisms underlying brain-behavior links—this potential has hardly been tapped to date.

The psychiatric consequences of specific brain disorders

Turning from the general to the particular, the following sections review a range of childhood brain disorders from a psychiatric perspective. Because we cannot cover the whole of pediatric neurology and neurosurgery in a few pages, disorders have been selected on the basis of frequency, severity or particular relevance to child psychiatry. The main clinical features of each disorder are reviewed along with the psychiatric consequences. For readers who want to learn more about specific aspects of pediatric neurology, we recommend Aicardi *et al.* (2009) or Piña-Garza (2013) for good accounts.

Epilepsy

Convulsions are the commonest problem encountered in pediatric neurology. At least one child in 200 experiences repeated epileptic seizures without a detectable extracerebral cause. This constitutes the usual definition of epilepsy. By "extracerebral" causes, we refer to conditions such as hypoglycaemic seizures (in context of diabetes) or anoxic seizures (associated with faints or breath-holding attacks). The definition also excludes the 3% of preschool children who have one or more convulsions provoked

by febrile illnesses. Febrile convulsions are usually benign; about 98% of affected individuals do not go on to develop persistent epilepsy. In practice, distinguishing epilepsy from other sorts of paroxysmal disorders (such as faints and parasomnias) can be surprisingly difficult. Misdiagnoses are all too common in both directions (Crompton & Berkovic, 2009).

Psychiatrists may be asked to help distinguish between “true” seizures and non-epileptic seizures. This is not an easy task. Most children with non-epileptic seizures also suffer from true seizures. Emotional stresses can precipitate true seizures; many children with true epilepsy have psychiatric problems too. Clinically, we seek to make the distinction on the grounds of behavioral observations. Pointers indicating that a child is having non-epileptic seizures include: occurrence when the child is being observed but not when the child is alone; a gradual rather than sudden onset; a paroxysm that involves quivering or uncontrolled flailing rather than true clonus; theatrical semipurposeful movements accompanied by loud screaming or shouting; the fact that painful stimuli are actively avoided during an attack and serious injury does not occur; the offset is sudden with an immediate return to an alert and responsive state. Finally, to determine with reasonable validity the nature of the convulsion, it will be necessary to establish whether or not the EEG shows any paroxysmal discharge during an episode. All these observations are easier to make when the child is assessed with combined EEG and video monitoring. None of the pointers is infallible; however, and some sorts of true seizures (most notably frontal lobe seizures) are easily mistaken for non-epileptic seizures (Cuthill & Espie, 2005; Caplan *et al.*, 2011).

For the purpose of deciding how to manage non-epileptic seizures, there are few treatment studies in children. The most promising treatments emerging from the adult literature include cognitive behavioral treatments that have been used successfully in other medically unexplained symptoms (see, for example, Goldstein *et al.*, 2010). Clinical consensus suggests incorporating a careful behavioral analysis of antecedents and underlying stressors, and remediation of these as far as possible. This should be followed by a focus on a consistent, calm and optimistic management approach. In general terms, everyone should deal with the child in such a way that they pay as little attention as possible to the attacks and avoid medical interventions.

The classification of epileptic seizures and syndromes has changed repeatedly over recent decades. In the current classification of the International League Against Epilepsy (ILAE), the most basic distinction in seizure type is between generalized and focal seizures (Berg *et al.*, 2010; see Figure 31.4). Generalized seizures are bilaterally generated and the first clinical symptoms do *not* suggest a focal onset. Examples of generalized seizures include generalized tonic-clonic seizures, absence seizures, atypical absences, tonic seizures, atonic seizures, and myoclonic seizures. In the recent reclassification of the epilepsies, it has been concluded somewhat controversially that no natural classification for focal seizures exists, therefore focal

Figure 31.4 Revised terminology and concepts for organization of seizures and epilepsies: report of the ILAE Commission on Classification and Terminology, 2005–2009. (From Berg *et al.*, 2010.)

seizures should be described according to their manifestations (e.g., dyscognitive, focal motor). Focal seizures arise in a single hemisphere and can generalize. The previous terms, “simple” and “complex” partial seizures, have been abandoned.

The link between epilepsy and cognitive impairment is complex (Reilly & Neville, 2011). Rates of intellectual disability (ID) (IQ < 70) in children with epilepsy range from 18% to 30%. We do not know for sure why the average IQ of children with seizures is reduced. Although it is often assumed that the seizures themselves cause neural disruption, there is an alternative viewpoint that proposes that seizures can be markers for adversity. That adversity is, according to this theory, the proximal cause of ID and can arise from family factors (social or genetic) or from other non-epilepsy related neurological abnormalities. Children whose epilepsy is associated with additional neurological abnormalities have a significantly lower mean IQ than children with idiopathic epilepsy. Lower IQ is also associated with early onset seizures, more frequent seizures, and with a longer duration of epilepsy (Kernan *et al.*, 2012). Permanent intellectual deterioration as a direct result of the seizures themselves is probably rare. Rasmussen’s syndrome (Figure 31.5) is an example of a rare, progressive (usually unihemispheric) epilepsy syndrome in which the impact of persistent seizures on the unaffected hemisphere is thought to contribute to the characteristically associated cognitive deterioration (Bien *et al.*, 2005).

Clinical studies suggest that cognitive impairment over the short term is associated with the frequency of seizures, with the presence of multiple seizure types, an early onset, and chronicity. On the other hand, the development of psychiatric disorders and behavioral problems over the longer term does not appear to be linked so closely to seizure burden (Jones *et al.*, 2010).

Figure 31.5 *Rasmussen's encephalitis*: Axial T2 MRI demonstrates atrophy of the left cerebral hemisphere. There is severe loss of white matter (white arrow) associated with damage of the left basal ganglia (black arrow) and thalamus (white arrow). Note significant progression of the disease over 4 years.

Two other factors are potentially relevant to cognitive impairments in children with epilepsy. Firstly, subclinical seizure discharges (as measured by EEG) are associated with significant impairments in cognitive processing in about 50% of individuals in whom they are recorded (Binnie, 2003). Secondly, antiepileptic medication may impair cognition too. Older drugs, such as phenobarbitone and phenytoin, are the worst offenders. Carbamazepine and sodium valproate are probably less harmful, particularly when given singly rather than in combination. Determining whether antiepileptic medications have an independent adverse impact on cognition is complicated by the fact that children with recent onset epilepsy, previously unmedicated, also have impaired cognitive functioning. Although most studies of cognition and epilepsy have focused on IQ, there is good evidence that children with seizures also have a high rate of specific learning problems *after allowing for their IQ*. These specific learning difficulties include language and reading problems (Rutter *et al.*, 1970; Kernan *et al.*, 2012).

Epilepsy in childhood is a powerful risk factor for emotional and behavioral disorders. In the Isle of Wight study (Rutter *et al.*, 1970), 29% of 63 children with idiopathic epilepsy had a psychiatric disorder. This was four times the rate in children without physical disorders and over twice the rate in children with physical disorders not affecting the brain. Davies *et al.* (2003) reported that 37% of an epidemiological sample of schoolchildren with epilepsy had at least one psychiatric diagnosis, compared with 10% of community controls. Although

children with epilepsy have a high rate of psychiatric problems, the nature of these problems is not particularly distinctive (with a few rare exceptions). Despite many attempts to establish whether particular types of epilepsy are associated with specific psychiatric problems, the presence or absence of associated neurological abnormalities provides a better predictor. In the Isle of Wight study, for example, psychiatric disorders were twice as common among children with epilepsy in the presence of additional neurological problems (Rutter *et al.*, 1970). Accordingly, some predictors of psychopathology, such as the frequency of seizures or the presence of generalized cognitive impairment, are probably just markers for the extensiveness of underlying brain abnormalities (Kanner *et al.*, 2012). Cognitive predictors of psychopathology therefore include impaired neuropsychological functioning and specific reading difficulties, the effects of which may be directly or indirectly related to mental health problems.

There is rather weak evidence that antiepileptic medication influences the risk and type of psychopathology, at least in adults (Piedad *et al.*, 2012). Few properly controlled trials have been performed, almost none in children. Antiepileptic drugs can have beneficial as well as adverse psychotropic influences. The impact of medication upon the risk of a psychiatric disorder such as depression is hard to distinguish in practice from reporting bias. Adults who are coincidentally depressed may report undesirable side effects of antiepileptic medication. If they reduce their medication as a consequence,

their seizure frequency may increase. If they are suffering from increased seizure frequency and severity they may be prescribed higher doses of antiepileptic medication. Higher doses may influence the risk and reporting of side effects. Directions of effect are therefore difficult to establish in the absence of properly controlled trials. The wise clinician will take seriously parental reports of behavioral or emotional side effects that could be due to medication and will monitor them carefully (Caplan, 2012).

Social pressures can also influence psychiatric adjustment in cases of epilepsy. One potential social predictor is the extent to which the child is rejected or stigmatized as a result of community prejudices about epilepsy. Peer rejection is, however, more often a consequence than a cause of psychiatric problems in children with epilepsy. Interrelationships between risk of psychiatric disorder, social, family and other risk factors are complex. There is increasing evidence that behavioral problems are present very early in the course of epilepsy (or even before its onset). In such cases, underlying cerebral pathology is probably a risk factor for both epilepsy and the associated psychiatric disorder (see Lin *et al.*, 2012 for a review).

The interested reader is advised to seek more detailed accounts of the epilepsies than we have been able to provide here. Wallace (2004) provides a good introductory text, and there is a three-volume textbook by Engel and colleagues (2007) for a more detailed and densely referenced account. References are only provided in this section for topics that are not well covered in the main texts. There are also several good charity websites that give valuable information (e.g., www.epilepsyaction.org.uk).

Cerebral palsy

Cerebral palsy (CP) is the single greatest cause of severe physical disability in childhood. The label refers to a heterogeneous group of congenital and early-acquired brain disorders that meet three criteria. First, the disorders are chronic rather than transient. Secondly, the underlying brain lesions are static, although the clinical manifestations may change as the child grows up (thereby ruling out progressive neurodegenerative conditions or brain tumors). Thirdly, the clinical manifestations include abnormalities of motor function. These motor defects are often accompanied by other clinical manifestations of brain abnormalities, including epilepsy, learning problems and sensory impairments. More recently it has become apparent that children with CP have up to five times the probability of neurologically intact children in the general population of developing emotional and behavioral problems of clinical significance (Parkes *et al.*, 2008).

In the Isle of Wight study (Rutter *et al.*, 1970), psychiatric problems were evident in almost half of the children with CP and related disorders. The likelihood of psychiatric problems was significantly increased by low intelligence and specific reading difficulties, both of which commonly accompanied the condition. If the child with CP also had epileptic seizures, the rate of psychiatric disorder was even higher (58% vs 38%). No specific type of

psychiatric disorder was associated with CP, though there was a hint that attention deficit/hyperactivity disorder was disproportionately common.

Hemiplegic CP has been the focus of many psychiatric studies (Goodman & Yude, 2000), making it the best-characterized type of CP from a psychiatric perspective. Hemiplegia is a relatively mild physical disability and most children with hemiplegia are of normal intelligence and attend mainstream schools. Even so, about half of all children with hemiplegia have at least one psychiatric disorder. A recent study of 270 children with hemiplegia found that over 70% had difficulties with emotional regulation, concentration, behavior and getting on with other people (Parkes *et al.*, 2009).

Childhood dementias and other conditions involving the loss of skills

Childhood dementias usually present with an insidious loss of skills. They are often accompanied by non-specific psychiatric symptoms. Child psychiatrists must learn to recognize these disorders at an early stage, so that the child can be referred to a pediatric neurologist. Some conditions, such as Wilson's Disease, are now capable of being treated effectively. Any delay in diagnosis and treatment can result in unnecessary and irreversible brain damage. We do not have firm data on the prevalence of childhood dementia, but estimates of 20/100,000 population have been made, of which at least one third are of uncertain etiology (Nunn *et al.*, 2002).

In cases of cognitive deterioration, until the organic basis is recognized, the child's problems may be blamed on his or her laziness, or on parental mishandling, causing unnecessary anguish and subsequent guilt or anger. If the disease were inherited, genetic counseling might avert the birth of a second affected child. Finally, once the diagnosis has been made, a child psychiatrist may be able to offer useful help to the child, the parents, and the siblings—and this help is much more likely to be accepted if the child psychiatrist referred the case on to a pediatrician for appropriate physical investigations at an early stage.

Although desirable, prompt recognition of a dementing disorder is undoubtedly difficult. Normal development often involves some degree of "two steps forward, one step back"; many children revert to more babyish ways when physically ill or under stress. It is often claimed that a high proportion of children with autistic disorders suffer early regression, within the first 2 years or so of life (see Chapter 51). While true loss of skills, particularly of language, is indeed occasionally verified, it appears likely that "regression" is in truth more often a plateauing of skill acquisition especially of language (Baird *et al.*, 2008).

Many psychiatric disorders can interfere with concentration or application at school, leading to a falling off in classroom performance. A marked loss of skills in several areas is more likely to be caused by psychosocial rather than organic factors. In some rare conditions, psychosocial and biological risk factors interact. The children of prostitutes or drug addicts are clearly at psychiatric risk for psychosocial reasons. On the other hand,

they are also at risk of HIV infection and its associated dementia (see Chapter 46). Children of a parent with Huntington disease have a 50% chance of carrying the gene themselves. Although the onset of typical symptoms is in adulthood, psychiatric problems are often prominent in those with a juvenile onset (about 10% of all cases). While movement disorders are a frequent comorbid symptom, the diagnosis may be missed in circumstances where there is abuse, neglect and disorganization—commonly encountered in affected families (Julien *et al.*, 2007).

In practice, an organic cause for cognitive deterioration needs to be considered (and appropriate referrals or investigations initiated) when the child meets one or more of the following three criteria:

- (a) Progressive loss of well-established linguistic, academic or self-help skills—with performance being well below previous levels even when the child appears content, motivated and not preoccupied. Psychometric testing is sometimes helpful, particularly if repeated measures are available.
- (b) Emergence of other features suggestive of a brain disorder, such as seizures, evidence of visual impairment, tremor or postural disturbance.
- (c) Risk factors for relevant genetic or infectious diseases, such as a parent with Huntington disease, or who is known to have HIV/AIDS. Clinicians who make a practice of reviewing their initial diagnostic formulation at regular intervals will be less likely to miss insidiously progressive disorders that initially present with apparently straightforward psychiatric symptoms.

The dementing disorders that are most likely to present to child psychiatrists are:

Batten's Disease (also known as Neuronal Ceroid Lipofuscinosis). The diagnosis refers to a group of inherited neurodegenerative disorders, most of which are autosomal recessive (www.bdsra.org). Child psychiatrists are most likely to encounter the juvenile form. It is the most common neurodegenerative disorder of childhood, affecting up to one in 25,000 births, and onset is between 5 and 7 years of age. The presentation is usually visual failure; the disease progresses to obvious dementia after a few years. Because the presentation is with an unusual symptom, if no obvious cause is initially found for the visual failure, the child may be referred for psychiatric assessment of “hysterical” blindness. Alternatively, the initial pediatric assessment may attribute the visual impairment to a non-progressive cause. Because cognitive decline is delayed, psychiatric referral may occur several years later when deteriorating schoolwork and non-specific behavioral problems (such as disruptive and aggressive behavior) are mistakenly attributed to the psychological consequences of blindness or family stresses. Seizures may occur fairly early in the disorder, but the emergence of hard neurological signs is usually a late feature. Causal genes have now been identified (containing several hundred mutations). Accordingly, genetic tests can be helpful in diagnosing the disorder and permitting the identification of carrier status in the parents (Kousi *et al.*, 2012).

Wilson's Disease is an autosomal recessive disorder of copper metabolism. It occurs in about 1/30,000 live births (www.wilsons-disease.org). The presentation in children at elementary school age is usually with progressive liver failure. Overt symptoms presenting after the age of 10 include neurological features, insidious dementia, or non-specific emotional or behavioral problems. Early neurological features include extrapyramidal and cerebellar signs. Dystonic movements and postures can be bizarre, unilateral and exacerbated by stress. Misdiagnosis of the condition as conversion disorder is all too easy. The key investigation is to ascertain whether urinary copper is high, while plasma copper and caeruloplasmin are both low. Ophthalmological examination with a slit lamp may reveal the pathognomonic Kayser–Fleischer ring on the iris. A liver biopsy is necessary in doubtful cases. The disorder can be treated successfully by copper chelation, and earlier treatment results in a better outcome. Genetic testing to assist in diagnosis and screen relatives is now available (Ala *et al.*, 2007).

Huntington Disease is very rare, although recent research has suggested that the prevalence in the UK population could be as high as 12.3/100,000 (Evans *et al.*, 2013). It is an autosomal dominant disorder that typically presents with chorea and dementia in mid-adult life (Ha & Fung, 2012; hda.org.uk). The juvenile form occurs in 5–10% of cases, with onset under 21 years. The early onset form is characterized by psychiatric symptoms accompanied by a motor disorder. Chorea may occur but a rigid Parkinsonian picture is more common. Epilepsy is an early feature in a substantial minority. The first presentation may be with disturbed or withdrawn behavior, including loss of interest in games and lessons. These psychiatric features are particularly difficult to interpret in the context of the marked psychosocial disturbance that is common in families where one parent has Huntington disease. The child's fear of developing the same disease may also be important. Just as a positive family history should not lead to the assumption of a positive diagnosis, a negative family history does not rule out the diagnosis as the presence of affected relatives may be concealed, may be masked by misdiagnosis or may not be apparent due to “non paternity.”

The substantial increase in identified cases in the United Kingdom over the past few years confirms that ‘hidden’ pathology does exist in the general population. Identification of the disorder in younger people with early or prodromal symptoms is important now, but will become more so if there are developments in disease modifying treatments that need to be started before the cerebral degeneration becomes advanced. Brain imaging may reveal atrophy; striatal atrophy and white matter changes predominate in the prodromal stages. Huntington's disease is caused by a CAG triplet repeat expansion in the Huntington's disease gene, huntingtin (*HTT*). Longer CAG repeats predict earlier onset, (Ross & Tabrizi, 2011). A simple genetic test can confirm the presence of the expanded repeat, although the timing and impact of testing needs careful specialist consideration with the family, particularly regarding

predictive testing of children (for a discussion of ethics, see Hawkins *et al.*, 2011).

Adrenoleucodystrophy is an X-linked recessive disorder, thus affects males primarily, although female carriers may have a partial phenotype. It is characterized by a combination of adrenal insufficiency, progressive dementia and neurological features (Moser *et al.*, 2007). Even within the same family, however, the presentation can be very variable. Adrenal failure predominates in some affected boys; dementia and neurological features predominate in others. The earliest manifestations include non specific symptoms such as restlessness, poor coordination, disruptiveness and deteriorating progress at school. Occasionally, the condition may initially be confused with ADHD, if the associated adrenal failure is not recognized. Unequivocal neurological abnormalities usually begin between 5 and 9 years of age. There are both pyramidal and extrapyramidal signs, together with convulsions, deafness or visual failure (sometimes due to cortical blindness). In cases where the child has adrenal failure, there will be diarrhea, vomiting, hypotension and pigmentation. Mild adrenocortical insufficiency may only be evident from the results of an ACTH challenge. A leucodystrophy with occipital predominance is often evident on brain scan. The combination of leucodystrophy and adrenal failure is pathognomonic. The diagnosis can be confirmed by high levels of saturated very long chain fatty acids in tissues and body fluids, and by molecular genetic tests for mutations in the ABCD1 gene. This rare, but devastating, condition is one where gene therapies hold promise in terms of modifying disease progression (Cartier *et al.*, 2009).

Treatment of psychiatric problems in children with brain disorders

The psychiatric problems of children with brain disorders can be treated in just the same ways as the psychiatric problems of neurologically intact children and biological treatments are neither more nor less useful. There is no empirical basis, for example, for expecting greater success in treating a child's disruptive behavior disorder with carbamazepine rather than with parent training simply because the child also has a brain disorder. Individual, family and school-based treatment approaches can all be helpful. Children with brain illness such as epilepsy are almost always excluded from randomized controlled trials of therapeutic interventions so there is little systematic information on response to psychological, or psychotropic drug, treatment. However, clinical experience suggested that children with epilepsy and an additional mental health problem such as oppositional defiant disorder, respond just as well, if not better, to the current best evidence-based interventions (parent training programs—see Chapter 37). Similarly, although there are very few studies, children with depression and epilepsy appear to respond well to antidepressants (Thomé-Souza *et al.*, 2007), and children with anxiety and epilepsy to cognitive behavior therapy (Blocher *et al.*, 2013). In each of these examples, the

treatment is an evidence-based intervention for these conditions in children *without* epilepsy, so should be the treatment of choice for children with epilepsy, until there is evidence to the contrary.

As far as drug treatment is concerned, four points are worth emphasizing. First, the indications for, and choice of, psychotropic medication differs little from standard practice (see Chapter 43). Secondly, epilepsy is not a strong contraindication to using antipsychotics or antidepressants even though these drugs may increase seizure frequency. In practice, an increase in seizure frequency is rarely a major problem and can often be countered by adjusting the dose of antiepileptic medication. Most of the second generation antipsychotic drugs such as risperidone are probably less likely than chlorpromazine to exacerbate seizures, while olanzapine and clozapine are better avoided if possible because they are associated with a particularly high risk of seizures. Thirdly, stimulant medication can be very helpful for children with ADHD who also have a neurological problem such as epilepsy. A recent trial has confirmed that methylphenidate appears to be safe and effective for children with epilepsy (Santos *et al.*, 2013). Finally, when children with epilepsy develop behavioral problems, changing the type or dosage of antiepileptic medication can sometimes help, although there are few systematic or consistent findings. Changes in antiepileptic medication should obviously be discussed with the child's pediatrician.

In summary, there is substantial evidence that children with a brain illness are likely also to have a psychiatric disorder. Above all, this association demands good collaboration between professionals to ensure effective detection and treatment of mental health problems. Some of the most common and impairing disorders of childhood such as anxiety can be treated successfully with methods that achieve 80% good outcomes. Such success is associated with some of the largest effect-sizes in medicine (see e.g., Walkup *et al.*, 2008). Parents and children, if asked, often rate the psychiatric disorder as having a larger negative impact on quality of life, than the physical condition, yet the mental health problem may be quicker and easier to treat. For example, one study which looked at a 5 year follow-up of children with epilepsy, and their quality of life, showed that presence or absence of seizures did not affect quality of life ratings. However, the presence of a psychiatric disorder was associated with significantly reduced quality of life, as rated by both parents and children (Baca *et al.*, 2011). Pediatricians may lack the time or skills to diagnose an associated psychiatric disorder, and even if they did detect such a disorder they are often unaware of its significant functional impact.

Mental health professionals are often alarmed by a clinical encounter with a child who has active epilepsy, or severe cerebral palsy. Their discomfiture distracts them from recognizing and treating coexisting mental health problems, because their initial response is to feel the child's problems lie outside their area of expertise. However, the most effective and acceptable services for children with brain illnesses are likely to have physical

and mental health professionals working closely together. Joint clinical discussions, in which each expert's professional skills are recognized and valued, should ensure that these children do not suffer the double-disadvantage of having both a neurological illness and an untreated, yet usually treatable, mental illness too.

PART III

Approaching the clinical encounter

A: The clinical assessment

CHAPTER 32

Clinical assessment and diagnostic formulation

James F. Leckman¹ and Eric Taylor²

¹Child Study Center and the Departments of Psychiatry, Pediatrics and Psychology, Yale University, New Haven, CT, USA

²Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Introduction

The goal of clinical assessments is to identify the presence of psychopathology and, if indicated, to make a diagnosis and to develop a plan to initiate treatment in partnership with the parents and/or other providers often within a larger system of care. This is a multistep process that involves complex and conscientious decision-making based upon the available evidence from multiple sources (Bostic & King, 2007; Rutter & Taylor, 2008). Beyond the nature and progression of the child's symptoms (past and present) within and across multiple contexts (somatic, family, peers, school, and cultural background), it is important to consider the child's developmental and medical histories, exposure to adversity (acute or chronic) as well as the child's strengths and abilities and the presence of protective and resilience factors that may impact treatment outcomes. Another important goal is the formation of a therapeutic alliance with family. An alliance is more than just being liked by the patient and the family, but involves negotiating to identify shared goals (Green, 2006). Consequently, the formulation and prioritization of treatment goals with the family should involve a collaborative, problem-solving, hypothesis-generating, and hypothesis-testing approach that is based both on the available scientific evidence concerning potential risks and benefits of specific interventions, and on the child's and the family's knowledge-base and their attitudes concerning various treatment options and opportunities. Consequently, clinical assessments often need to include a psychoeducational component. Less frequently, clinical assessments of children and adolescents are conducted in a more focused and circumscribed fashion to address immediate safety, forensic, or research issues. Regardless of the scope, clinical assessments of children and adolescents are complex in nature and vary a good deal across the globe.

This chapter addresses each of these assessment components (Table 32.1) before moving on to consider the diagnostic process

and initial treatment planning. We begin by addressing the reasons for the referral and the need to understand the intentions of the person or agency requesting the clinical assessment.

Initial questions regarding referral

Children are usually referred to practitioners by someone with a focused question in mind. Clarity about why the referral was initiated (and by whom) is an essential ingredient for the evaluation to be a success. Children rarely initiate the referral and often their presenting symptoms are a greater source of concern for the parents or others in their environment than they are for the child. Many clinicians, based on their training and a traditional medical model of care, may choose to focus on whether or not the child meets criteria for a particular disorder; but this question may not be foremost in the mind of the person making the referral. For example, parents are often proactive in seeking the assessment based upon their worry that the child's current symptoms may portend the emergence of a more serious mental disorder that is thought to run in the family. The child's behavior at school may be much more problematic than it is judged to be at home. Not infrequently, the parties involved may not view the situation in the same way. Parents may be seeking special services or be in need of an evaluation for the child to return to school. In other instances, the referral source may be asking for an opinion concerning the legal status of the child—whether the child should be removed from the family or what the custody arrangements should be (see Chapters 19 and 49). Because of this broad range of possibilities, procedures need to be in place to clarify questions about the referral (Kanner, 1957; Rutter, 1975). Who made the referral? What prompted the referral? Are there differing points of view concerning the need for a clinical assessment? What are the key questions to be addressed? Are there clear administrative issues that need

Table 32.1 Basic elements in child and adolescent psychiatric assessments.

Content	Informant	Resources	Goals
Reason for referral; <i>Why this child? Why now?</i>	Parent, guardian, school personnel, and health-care provider(s)	Referral letters and conversations from school personnel and other health-care providers	Clarity concerning reasons for the assessment; Potentially different perspectives; Opportunity to build therapeutic alliance; Initial opinions concerning potential treatment options
Child's strengths, talents and interests and environmental supports How the family members interact with one another <i>Who is this child?</i>	Parents, child, other family members, peers, teachers, coaches	Parent- and self-reports about areas of interest and excellence Nature of the observed interactions between and among family members	Clarity concerning how the child is viewed within the family Opportunity to build trust and establish a therapeutic alliance and promote resiliency
History of present illness Comorbid conditions; Past psychiatric history and treatment response <i>What is the nature of the problem?</i>	Parents, child, other family members Past psychiatric evaluations and mental health records	Review of parent-, teacher- and self-reports; questionnaires; diagnostic interviews; videotapes Previous evaluations, therapies, treatments, medications (including dietary supplements); hospitalizations	Clarity concerning the course and function of the symptoms, accommodation, intervening stressors or associated changes in life circumstances Success of prior interventions Initial impressions concerning treatment priorities
Developmental, educational, and medical history	Parent, guardian, school personnel, and health-care provider(s)	Review of birth and pediatric records; education evaluations (see Chapters 35 and 42)	Presence of developmental or medical disorders as well as traumatic events that may have an impact on the child
Family history	Parent, guardian, school personnel, and health-care provider(s)	Review of structured and unstructured questionnaires; Genogram (see Chapters 24 and 28)	Presence of familial vulnerabilities relevant to prognosis
Home, school, and community environment	Parents, child, other family members	Parental self-esteem and psychopathology, parental strain, partial discord, sibling conflicts, level of hubbub, computer/video games, access to the internet; family resources including pets and neighbors (see Chapters 26 and 28)	To inform intervention strategies and identify challenges that will be faced by the treatment team; potential targets for adjunctive interventions
Mental Status examination	Child	Structured assessments of appearance, mood, orientation, adaptive functioning, attention, memory, fund of knowledge, judgment, insight, thought (coherence, speed, and content)	Assess the child's interaction with the clinician; screen for overt psychiatric symptoms that impact the child's behavior, adjustment and cognitive functioning
Neuropsychological evaluation	Child	Optional standardized assessments of intelligence, memory, receptive and expressive language, reading, executive function, visuo-spatial skills and motor coordination (see Chapter 34)	Clarify nature of the child's interaction with the psychologist; characterize the child's pattern of cognitive, linguistic strengths and weaknesses relative to same aged peers
Physical and neurological examination, laboratory testing, electrophysiological assessment and brain imaging	Child	Optional examinations to identify body dysmorphic features and evaluate the child's somatic, metabolic, and neurological status as well as brain structure and function (see Chapters 11, 24, and 35)	Identify any genetic, medical, metabolic, endocrine, or neurological disorders that may impact the child's course of illness and treatment

to be considered? Based on the answers to these questions, one should also consider whether the assessment team that has been approached is the one best suited to undertake the assessment. For example, depending on the clarity of the issues and the health-care system, it may make sense to refer the family on to another provider with greater expertise who is better positioned to intervene with the appropriate services.

Many of these questions can be clarified by direct contact with the referral source and by review of any relevant documents. If privacy and confidentiality can be assured, direct contact by telephone or via the internet may be of great benefit and lead to requests for additional information. Many clinicians and health-care systems have found the use of structured and semi-structured questionnaires and well-validated parent, teacher, and self-reports to be invaluable in preparing for clinical assessments. Some of the widely used parent-report instruments with excellent psychometric properties provide a preliminary assessment of the child's mood and anxiety level, attentional and disruptive behavioral problems, and the child's perceived level of psychosocial stress as well as the parents' well-being, the home environment and the level of caregiver strain (see Chapter 33). At times this information may point to other important problems that had not been previously identified and that need to be considered during the course of the evaluation. It is also often helpful to ask families for prior authorization to contact other relevant parties (school personnel and primary care providers).

At the beginning of the in-person assessment, practitioners often use open-ended questions such as, "Because we want to be sure to address your primary concerns, please briefly tell us how we can best be of service to you." Typically, the parents are asked this question with and without the child present and the child is asked as well. Questions of this sort, as well as other efforts to gain greater clarity concerning the motivation to seek a clinical assessment can also be very useful in setting the stage for the development of a positive therapeutic alliance, which has been shown to be associated with improved outcomes for both children with disruptive behaviors and those with severe anxiety (Kazdin & Durbin, 2012; Marker *et al.*, 2013).

Observations of the family

Attitudes to referral, disorder and treatment

From the initial contact with the family, it is important to be attentive to the nature of the parents' attitudes to their child and to each other as well as to the professionals involved in the case. For example, did the mother or father take the lead in making the referral and deciding on the timing of the assessment? How did they describe their child and were there any hints as to the nature of the communication between the parents? What are their fears and expectations? How important is the family's cultural background as they consider their child's difficulties? Clinicians should be attentive to these attitudes throughout the assessment and initial treatment planning. Often they shift to

some degree as the assessment process takes place and as the family recognizes the inherently collaborative nature of the process. When clinicians show respect and a positive attitude during the assessment, it can make a difference.

Patterns of interaction

Among the sources of information that the clinician has available during the assessment, one of the most important is the nature of the interactions within the family. Patterns of dyadic reciprocity, sensitivity, and intrusiveness are often remarkably stable over the course of development (Feldman, 2010). Opportunities to observe these interactions abound beginning with how the family members position themselves in the waiting room and where they choose during the interview assessment.

Regardless of how the later stages of the assessment are organized, it is often beneficial to have a brief meeting with the family all together to explain what will be taking place and to sort out who will be seeing whom for what purpose. This is another time to closely monitor the nature of the verbal and nonverbal communication among the family members. After welcoming the family, making any further introductions, and thanking them for coming in and filling out the questionnaires and parent-reports, some clinicians have found that asking the parents to "brag" about their child is a useful starting point. "What talents and favorite activities does your child have?" This can usefully engage the family and set the stage for a successful encounter as well as providing clues as to how one might foster resilience in the child and the family (see Chapter 27). Each of the family members should be asked to share their perspective (Brown & Rutter, 1966). The clinician may ask, "What questions do you have for us? We will do our best to answer each of them before you leave today." Other open-ended questions such as, "I wonder how much you have talked together about why you are here to see us?" or "Have you had a family discussion about your reasons for coming in today?" or "How did you feel about the referral?" are often more informative than making more specific inquiries. This approach also provides opportunities for the clinician to observe interactions among family members as well as to identify any conflicting viewpoints that will need to be reconciled if the recommended interventions will be adhered to and successfully implemented. Depending on the age of the child, some of these questions should be repeated when the child is no longer in the room.

Naturally, during this initial portion of the interview when the family is together, care needs to be taken to make the child feel as comfortable as possible. For younger children, the availability of toys, paper and crayons, and other play materials, for example, Lego, makes good sense. Access to videogames on the parents' cell phone may be more problematic and distracting. Whatever the circumstance, observing what the child decides to do and how they interact with their parents and the clinician at the very beginning of the assessment can be informative. Likewise, if the child becomes distressed or starts to display disruptive behavior, this provides another opportunity to monitor the

parent's response as well as to intervene in a sensitive fashion by encouraging the parents to respond in a way that they find the most appropriate.

Basic elements in the diagnostic clinical assessment

Other key elements in the assessment include interviewing the child and interviewing the parents. The sequence and organization of these interviews depend on the child's age and developmental level as well as the clinician's best judgment about how best to proceed.

Interview with the child

The cardinal aim of the interview is to help the child relax with the interviewer and to lay a foundation of trust (Nurcombe, 2008). Without trust little can be achieved. If a modicum of trust does develop, the clinician will be able to ascertain how the child perceives problems in his or her life, evaluate the child's affect and capacity to relate to the interviewer, and catch a glimpse of his or her family life. The age, developmental level, personality, and expectations of the child matter and will shape the course and content of the interview.

The clinical assessment of young children differs fundamentally from that of adults and adolescents. While it is useful to monitor the child's behavior and social interactions in various contexts including when the parents are present, it is also crucial to interview the child separately. Care needs to be taken to minimize the child's distress when being separated from their parents. This can be performed by reassuring the child that they can be reunited with their parents as needed. The child also needs to see exactly where their parents will be located during their interview. If the assessment is being completed by a team of clinicians, often the parental interview will occur simultaneously with the child's interview. Under such circumstances, having the parents accompany the child to the room set aside for his/her assessment makes sense and can be a source of comfort for the child.

For younger children, the opportunity to play and interact in a less structured fashion with the clinician can help put the child at ease. For example, asking the child to talk about what they enjoy doing and to elaborate on the areas identified as strengths and interests is a good place to start. Having an on-going activity, for example, drawing a picture or building something with Lego, permits the child to respond more spontaneously and openly to the clinician's queries. Intermittently praising the child's work and positioning oneself at the child's eye-level, that is, sitting on the floor, can facilitate the dyadic interaction between child and clinician. Some clinicians find it helpful to ask the child questions such as, "If I were a magician and could give you three wishes, what would those be?"

Eventually the clinician will need to address the behaviors and emotional issues that prompted the referral. People of all ages are open to the influence of suggestions, but none more

so than young children. Open-ended questions will work the best and be the least prone to distortion and suggestion: "What did your parents say about why you were coming in to see me today?" "What is most upsetting to you?" "What do you wish might be different?" "Is there anything you worry about every day?" Moreover, when assessing any symptom, to ask the child to give it a rating out of 10, where zero is "not a problem" and 10 is "awful, couldn't be worse" can provide a baseline for future assessments. Once the child provides some insight into their difficulties, it will be important for the clinician to contextualize the problem in terms of where and when and in relation to whom these problems occur. "How does your mom respond when that happens?" "Do you remember what was going on just before that happened yesterday?"

The issues for older children and adolescents vary and may reflect their reluctance to be open with an "adult" who is likely to try to impose their will. While it is almost always possible to establish rapport and collect information from adolescents, it can be a challenge. Being respectful and curious about the adolescent's perspective is important. While it is important for the assessments of children of all ages to have an appropriate degree of structure and standardization, the clinician also needs to be open to the unexpected. Otherwise, important information and insights may be missed (Cox *et al.*, 1981; Rutter *et al.*, 1981; Cox & Rutter, 1985). Variations in the style and content of the interview may differ considerably depending on the child's symptoms, and on cognitive and sensory impairments, if any (see Chapters 47 and 51–72). The interview with the child will also include many elements of the mental status examination (see later). At the end of the interview, the clinician should review with the child what they have both learned about the child's reasons for being seen and how he or she feels about it.

Parental interview

The parental interview is focused on the child's presenting problems, medical and family history, early development, school progress, and peer relations as well as on gathering information concerning the home and family environment including the parents' child rearing techniques and the methods of discipline used (Table 32.1). The best place to start is to address the **reason for referral** and determine what it is about the child's behavior, feelings, or social interactions that are of the greatest concern to the parents and what prompted the assessment. How do the parents understand their child's problems?

Context is critically important. How predictable are the symptoms in a given set of circumstances? How much do they vary depending upon which parent is there or which class the child is in? Are there other contextual features that appear to make the situation better or worse? Identifying specific antecedents and precipitants can provide valuable clues to what *function* the symptoms have. What has been the parents' response? Anxiety in children will often trigger behaviors in their parents. At times the parent's efforts to comfort and reassure the child can have unforeseen negative consequences by providing a

form of reinforcement that may lead the symptoms to persist and intensify. Although accommodation of this sort has been studied extensively in Obsessive-compulsive disorder, it is commonplace among other pediatric onset anxiety disorders (Lebowitz *et al.*, 2013). How have others in the family or at school responded? What has worked in the past and what has not? Is there any hint of secondary gain? Here it is important to move beyond general answers (such as mentioning efforts to comfort, admonish, or punish the child) and to obtain a more detailed sequential account of how this has been performed and how the child responded. Often asking the parents to recall specific recent episodes can be useful. This can provide some clarity about how things have progressed from the onset and if there were any precipitating events or predisposing factors. It is important to ask for detailed examples of the child's symptoms from the last week, and then determine if these were typical of the past month as well.

Do these symptoms reflect an underlying disorder or do they reveal problems within the child's environment? It is also important to be vigilant about the parents' state of mind and their possible embarrassment, ambivalence, or shame in seeking professional advice. "What did we do wrong?" "Is it my fault?"—are common unspoken questions. Echoes of the parents' memories of their own experiences while growing up are often part of the unspoken dialogue.

Beyond the immediate reason for referral, the assessment team also needs to consider the presence of any co-occurring symptoms as well as any significant past psychiatric and neurodevelopmental problems. Many services now ask parents to complete questionnaires to screen for possible co-occurring conditions, but clinicians still need to be alert in the course of the parental interview to the presence of co-occurring symptoms and past disorders.

Next, asking the parents to review their child's developmental history will allow the clinician to gain a clear perspective on the child's somatic, psychomotor, neurocognitive, linguistic, social, temperamental, and emotional development. Parents can vary a great deal in terms of their ability to recall specific developmental milestones. Often it is useful to ask the parents to complete a structured questionnaire and for the clinician to review this information prior to the time of the in-person assessment. This will allow the clinician to be knowledgeable and relatively expeditious.

It is also important to review the child's educational history, starting with nursery and kindergarten. Then in later schooling, what did the parents hear from the teachers? What were their peer interactions like? How easy was it for them to make good friends? What pastimes did they enjoy most and excel at?

Another important component of the parental interview concerns the child's medical history. Major influences on neural development occur during embryonic and fetal development (see Chapter 9). Consequently, this history needs to proceed from conception and include any difficulties the mother had in becoming pregnant and the use of any interventions (such as

in vitro fertilization), any pregnancy and birth complications including the mother's emotional state and level of psychosocial stress during the pregnancy. The parents' smoking habits, alcohol consumption, and use of illicit drugs should also be included in the medical history. Chapter 35 describes the detection of physical illness and injury, past and present. Allergies should be carefully documented and results of previous medications noted.

The mental status examination is another essential part of the initial clinical assessment. It includes a description of the child's appearance; patterns of interaction; current affect and reactivity; orientation to person, place and time; attention and apparent intelligence; fluency of speech; and the speed, coherence and content of the child's cognitive processes. The mental status examination also serves as a useful opportunity to screen for organic or neurological conditions and serves as a prelude to conducting further psychological, medical, and/or neurological examinations (see Chapters 34 and 35). Although the mental status examination is conceptualized as being distinct from other portions of the assessment, it serves to summarize the clinician's impressions from the interviews with the family and with the child. Some components, however, do require specific inquiries (such as the child's orientation to person, place and time, and their fund of knowledge and memory).

Finally, while some clinicians prefer to conduct the entire diagnostic assessment in a conjoint family setting, in our view this approach has some inherent disadvantages. Context matters and individuals do not behave the same when everyone in the family is present. Indeed, there are circumstances when spending time with each parent individually can be important: as in the case of parental divorce and joint custody arrangements. Some time spent with each parent may be useful even if there is no obvious discord between them. However, being open to the parents' preferences in this matter also makes good sense especially as the team continues to build a therapeutic alliance collaboratively with the parents and child and attends to the treatment priorities (Cox *et al.*, 1995).

School reports and direct contact with teachers

After securing parental agreement and in advance of the initial interview, it is useful for the clinician to review school reports. This is particularly true of reports related to academic performance and any special education services that the child may currently be receiving or received in the past. Children may behave differently in the classroom or in other school settings than they do at home. Educational difficulties are frequently associated with psychopathology, and parents and teachers may only partially agree on the presence of particular symptoms such as inattentiveness, hyperactivity-impulsivity, and oppositionality (Bussing *et al.*, 2008). While there are advantages to using standardized teacher-report questionnaires (see Chapter 33), it also is useful to have teachers express their own concerns and report on the child's behavior and response to directives. If special services have been provided, it is important to review

their impact on the child's behavior and academic performance over the course of time. Being attentive to cultural differences in the educational context is also important especially if the child has recently relocated from their home country. Even with the teacher and school reports in hand, it is often the case that specific queries will arise that will prompt a member of the assessment team to contact the school personnel directly. In some instances, if there are persistent differences of opinion concerning the child's behavior at home and at school, visits to observe the child in both settings may be useful. Efforts to build a collaborative alliance with the teachers and other professionals at the school will bode well for the child's outcome. This is particularly true as the initial treatment plan is developed and implemented due to the fact that some treatment components may focus on the school environment in terms of advocacy, services, accommodations, opportunities for resilience, or simply monitoring changes in the child's behavior over the course of treatment.

Psychological testing and medical assessment

These important aspects of assessment are reviewed in Chapters 34 and 35. The initial assessment needs to be informed by knowledge of previous assessments and screening (e.g., for hearing) and there must be enough expertise to appreciate when there is a need for further referral.

Standardization of clinical assessment

Standardized approaches and the use of structured interviews, rating scales, and observational methods constitute an important part of a clinical assessment (see Chapter 33), but there is also a clear need to look beyond the diagnostic formulation to consider factors that might be important in the causation of the disorder and its course and prognosis and that inform therapeutic planning.

Viewed from a global perspective, the availability of standardized interviews is a step forward. This is particularly true in many parts of the world where child and adolescent mental health professionals and other clinicians are forced to make decisions about diagnosis and treatment in imperfect situations within a limited time period and with incomplete information. For example, the Development and Well-Being Assessment (DAWBA) is a package of interviews, questionnaires, and rating techniques designed to generate ICD-10 and DSM-IV psychiatric diagnoses on 5–17-year-olds based on information provided from multiple informants (parents, youth over 11-year-old and teachers) and is now available, free and with computer algorithms, in more than 20 languages (Goodman *et al.*, 2000) (<http://www.dawba.info/a0.html>).

However, there are clear downsides to being overly reliant on diagnostic instruments. One reason for caution is the high frequency of idiosyncratic but clinically significant information that may be missed. Despite recent efforts to revise and validate the DSM and ICD diagnostic categories, they remain imperfect (see Chapter 2). Additionally, the much debated and carefully

chosen wording of these criteria rarely matches the complex presentations of the children referred for assessment.

As it formulates a narrative concerning the nature of the child's problems, the assessment team needs to consider how a given child's symptoms resemble those observed in other children as well as what aspects of the presentation are unique to this child and this family. These considerations will allow them to frame an initial set of hypotheses concerning what factors will influence response to treatment while building a strong therapeutic alliance. This is a key step in the problem-solving, hypothesis-generating, and hypothesis-testing approach needed to formulate and prioritize treatment goals with the child and the family.

Presence/absence of clinically significant psychopathology

Formulation in child and adolescent psychiatry is a complex and iterative process that distills the information from multiple sources into a meaningful narrative and establishes a set of hypotheses about the child and his or her presentation that then helps to shape the initial treatment priorities. One basic question underlying this process is whether or not the child's problems are clinically significant. One of the hallmarks of many psychiatric symptoms is their dimensional character and continuity with normal emotional and behavioral states. Care needs to be taken not to "pathologise the normal." This raises the important issue of how to establish thresholds that distinguish developmental normal traits and emotional states from those that are indicative of pathology. Relevant questions include: Does their intensity go beyond the range of normal variation given the child's age and temperamental predisposition? Do these symptoms reflect a clear substantial change from the child's usual emotional state? Are they pervasive across interpersonal and social contexts? How much time do they consume in a typical day? To what extent can the child control these symptoms by means of distraction or engagement in pleasurable activities? Many of these questions are embedded in symptom-specific rating scales. These scales allow clinicians to better characterize each child relative to other children with similar problems across a range of symptom dimensions including anxiety, obsessive-compulsive, manic and depressive symptoms as well as symptoms of post traumatic stress disorder, motor and vocal tics, and attentional and behavioral symptoms, among others (see Chapter 33). Repeat assessments with these instruments can provide an important tool to clinicians so that they can regularly monitor the child's progress. Despite the potential benefits associated with the use of these scales, they are no substitute for the practitioner's clinical judgment concerning whether or not the presenting symptoms are clinically significant. In addition, the usefulness of these scales may be limited depending on the child's age, the need for specific informants (parent, teacher, self, and expert clinician), the variable time periods that are assessed (current, past week, past 6 months, etc.), idiosyncratic

scoring paradigms, their potential cost, and, in some cases, the need for formal training to establish the rater's reliability.

In other instances, clinical interventions may not be indicated even if the level of distress is high. For example, a serious grief reaction following the death of a loved one is quite common and a source of distress. In some cases, the emotional distress of the parents and family members contributes to the intensity of the child's reaction. The passage of time and supportive counseling may be sufficient (see Chapter 36).

Finally, the assessment team may determine that although the severity of the presenting problem is not great enough to warrant an immediate intervention, it is clinically significant. This is true of many medical disorders as they herald recurrent difficulties and an increased likelihood of a range of negative health outcomes, for example, high blood pressure. Many neurodevelopmental disorders are chronic conditions which require long-term monitoring and interventions across a number of contexts (home, school, and social). The waxing and waning course of tic disorders is a good example. Often parents or the primary care provider will request a consultation when the tics are severe, but by the time the child is observed in evaluation they have all but disappeared (Leckman, 2002). Here psychoeducational interventions with the child, the parents, school personnel, and peers, concerning the nature and course of tic disorders may be indicated (see Chapter 56).

Assessment of psychosocial impairment and safety

Efforts to determine the degree of impairment in psychosocial functioning are another key consideration in establishing the clinical significance of a child's presenting symptoms. From the time of the Isle of Wight studies onward, the assessment of impairment has been a standard part of the assessment of children and adolescents (Rutter *et al.*, 1970). The need to establish the level of psychosocial impairment associated with various forms of psychopathology was given further impetus by subsequent epidemiological surveys that reported remarkably high prevalence rates of psychiatric disorders (Kessler *et al.*, 1994). This in turn directly led the developers of DSM-IV (American Psychiatric Association, 2000) to incorporate a clinical significance criterion in more than 70% of all diagnostic criteria. The precise wording varied but generally followed: "The disturbance causes clinically significant distress or impairment in social, academic, occupational, or other important areas of functioning." Not surprisingly, the inclusion of this criterion dramatically reduced the prevalence rates for many disorders and increased the proportion of cases likely needing mental health services. The debate continues and the clinical significance criterion has been removed from many of the DSM-5 diagnostic criteria (American Psychiatric Association, 2013). It is therefore all the more important that the presence and degree of impairment are noted separately and consistently. Are the features of the disorder(s) distressing the child? Is their school

work suffering? Are they held back from social activities, or victimized, or unable to make friends?

The assessment of safety is another important topic. In the case of younger children, this may focus on the child's risk of injury as a result of abuse or neglect (see Chapters 29 and 30). For older children and adolescents, the assessment concerns the risk of violence to self or others (see Chapters 49 and 64–68). In some instances, the referral itself may have been prompted by these concerns. If so, the person making the referral will often be directed immediately to seek emergency services which in turn may lead to psychiatric hospitalization or to the involvement of government agencies charged with protecting the safety of the child and of specialized forensic assessment services. In any case, the clinical assessment team, in nonemergency settings, needs to be alert to issues of safety. Based on the information provided by the child and the parents, the clinician may need to determine whether the child or others is in immediate danger. Relevant information includes the presence of current or past ideation or acts that indicate a significant risk to self or others as well as a range of risk factors (explicit plans, cognitive distortions, mood state, impulsivity, personality, and a range of environmental stress factors involving family psychopathology and conflict) (see Chapter 64). In addition to self-harm with clear suicidal intent, acts of intentional self-harm (cutting, burning, etc.) to provide temporary relief from intense dysphoria have become more common over the past two decades among adolescents and young adults (Zetterqvist *et al.*, 2013). Acts of nonsuicidal self-injury need to be carefully documented and understood and, if present, need to be considered in the formulation of the initial treatment plan. Other serious risks during adolescence include unplanned pregnancies due to reckless and hypersexual behaviors associated with bipolar disorder (see Chapter 62).

Duration and timing of disorder

The duration and timing of psychopathological states are two other features that contribute to an understanding of their clinical significance. Many diagnostic classification systems specify a duration criterion—the minimal time period the symptoms need to be present in order for a diagnosis to be made. In the case of DSM-IV and DSM-5, the panels of experts came up with a very broad range of required periods, currently: 2 weeks for major depressive disorder; 3 months for bulimia nervosa; 6 months for generalized anxiety disorder, 12 months for conduct disorder; and 2 years for persistent depressive disorder (American Psychiatric Association, 2000, 2013). While these time periods are based on the consensus of experts, they remain opinions and are somewhat arbitrary. For other diagnoses, such as ADHD, the DSM criteria specify that the symptoms being considered must have been present prior to a certain age. In many instances, establishing a clear onset or estimating the duration can be problematic given the retrospective nature of the information provided by multiple informants and concerning multiple potentially interrelated psychiatric symptoms. Apart from possible reporting biases,

it may well be that many psychiatric disorders do not, in fact, have a clear-cut onset. Frequently, symptomatology gradually builds up over time when new symptoms become evident or when psychosocial impairment is manifested (Sandberg *et al.*, 2001). By contrast, other disorders are defined in part by their sudden, overnight onset, for example, the recently proposed pediatric acute-onset neuropsychiatric syndrome (PANS) (Swedo *et al.*, 2012). While clinicians need to take the necessary time to clarify as much as possible the onset, course and timing of the presenting symptoms as well as the points of remission and exacerbation, this is usually an imperfect science. As a consequence, a slavish adherence to diagnostic criteria that specify symptom duration makes little sense.

In sum, the process of determining whether or not the child's problems are clinically significant requires the assessment team to distill information from multiple sources into a meaningful narrative and to establish a set of hypotheses about the nature, origin (onset), course (exacerbations and duration), and current severity (impairment) of the child's presenting neurodevelopmental, emotional, and behavioral symptoms.

Diagnostic formulation: integration and synthesis

As noted earlier, formulation in child and adolescent psychiatry is a complex and iterative process that distills information from multiple sources into a meaningful narrative and establishes a set of hypotheses about the child and his or her presentation that then shape the initial treatment priorities. What symptoms are causing the greatest degree of difficulty for the child and for others in his or her immediate environments? When and why did these problems arise and how long have they been present? What can be done to ameliorate them? Are there any proximal risk mechanisms that, if addressed, might have a positive impact? What else is going on in the environment (acute or chronic stressors, etc.) that is having an impact on these symptoms? What new knowledge could we provide that would be useful for the family and others directly involved in the case (peers, teachers, etc.) to be aware of, for example, evidence-based knowledge concerning the natural history, treatment, and prognosis? Can everyone agree regarding the nature of these difficulties and what the best course of action would be to address them?

Diagnoses are one element in this formulation and they provide a succinct summary of some aspects of what has been learned over the course of the evaluation. Ultimately, the clinician's judgment in integrating all the available information into a "best estimate" diagnosis is key (Leckman *et al.*, 1982). However, care needs to be taken not to "reify" the diagnosis. When a specific disorder is reified by the clinicians, there is a risk that the child is no longer viewed as a unique human entity but is instead viewed as "a case of X disorder." We need to focus on "the whole child" including his/her strengths, interests and abilities, not just his/her "diagnosis."

Diagnoses allow for "informed" communication between professionals and researchers, for example, what interventions have the strongest evidence base for a specific disorder, or as record keeping, for example, health-care systems that need to monitor the prevalence of disorders as well as track service delivery. In putting the clinical information together to establish a set of hypotheses about the child, the clinician needs to consider the source of the information and the context within which it was obtained. In cases of divorce and parental discord, the parents may not agree even with regard to the presence of specific symptoms or their importance. Parents, teachers, and other informants may also disagree on the importance of specific symptoms. It is also important to consider the knowledge-base of the informants. Are there other family members with a similar condition and how did this condition impact that individual over the course of his/her life? How much information has the family gleaned from various sources including the internet and how accurate is their understanding of the condition and its course and treatment? Given the iterative nature of assessments and treatment planning, the clinician always needs to ask—what information am I lacking and what would be the best source(s) to gain a more complete view of the child and a deeper understanding of their psychopathology?

Psychoeducation

Psychoeducation can be a key ingredient leading to a successful intervention. Given the incremental advances in our understanding of the etiology, course and treatment of childhood-onset psychiatric disorders, providing families with accessible, user-friendly sources of information can be enormously helpful (Lucksted *et al.*, 2012). Most involved family members of children and adolescents with mental illnesses need information, assistance, and support to best assist their ill family member and to cope with the challenges posed to their family system. Ideally, this information will include content about the nature of the disorder (etiology, course, and outcome), as well as expanding social support networks. For example, in the case of Tourette's disorder, familiarizing the family (and in some instances teachers and peers) with the existence of premonitory sensory urges and the momentary "sense of relief" experienced by many individuals suffering from this condition is truly enlightening and sets the stage for a greater level of interest and acceptance of recommendations to initiate cognitive-behavioral therapy (CBT) such as Habit Reversal Training (see Chapter 56; Martino & Leckman, 2013). Advocacy organizations are often an excellent source of such information. Indeed, providing the parents with the web links to such organizations can be very helpful and may initiate an interconnection that will be useful to everyone involved.

Another dimension of psychoeducation, for both the clinician and the family, is the need to be acquainted with the available evidence concerning the efficacy of various therapeutic

interventions. *Evidence-based medicine (EBM)* is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. This evidence includes meta-analyses of the relevant clinical trials in an effort to guide clinical practice. EBM has driven a transformation of clinical practice in medicine and has been adopted by major organizations including the center for Evidence Based Medicine (<http://www.cebm.net/>) and the Cochrane Collaboration (<http://www.cochrane.org/>). EBM seeks to assess the strength of the evidence regarding the risks and benefits of treatments (including lack of treatment) and diagnostic tests. Evidence quality can be gauged based on the source type (from meta-analyses and systematic reviews), as well as other factors including statistical validity, clinical relevance, currency, and peer-review acceptance. EBM recognizes that many aspects of health care depend on individual factors such as quality- and value-of-life judgments, which are only partially subject to quantitative scientific methods. In addition to EBM resources, clinical practice guidelines are also available from professional organizations including the National Institute for Health and Care Excellence in the United Kingdom and the American Academy of Child and Adolescent Psychiatry, and the European Society for Child and Adolescent Psychiatry, among others. The decision on which course of action to follow remains subject to input from personal, political, philosophical, ethical, economic, and esthetic values as well as the imperative to minimize the potential for doing harm to the child.

Treatment planning

Once the assessment nears completion and a meaningful narrative has been formulated that summarizes the information from multiple sources, the next step is to build a consensus and to propose a set of hypotheses that can be tested. Following a range of psychoeducation interventions, the clinician and the family are ready to embark on treatment planning. Although setting forth a “diagnosis” is important, relying solely on the “diagnosis” to guide a treatment plan can be problematic (Rutter, 2011). Seldom does our current state of knowledge allow for “the diagnosis” by itself to dictate the intervention. For example, if Johnny’s (an 8-year-old boy) increasing separation anxiety at home and his increasing social isolation and, at times, his disruptive behavior at school are based, in part, on his parents’ hostile estrangement from one another and on his need to transition back and forth between two residences, then it may make sense to engage the family in a therapeutic intervention that seeks to help the parents recognize the negative consequences of their hostile interactions on their child and to provide a neutral therapist to explore with the child his or her understanding of the situation (see Chapters 26, 39, and 40). This in turn may help the estranged parents refocus on their child and find ways to support and celebrate jointly the child’s interests and abilities. By contrast, if the child’s anxiety is long-standing and a reflection of a shy or

inhibited temperament manifested by being socially awkward, withdrawn, and avoidant, a course of CBT or pharmacotherapy or both may be indicated depending on the family’s willingness to pursue one of these interventions (see Chapter 60). Other principles that are key to treatment planning include: safety (to do no harm); building on the child’s strengths (as a way to foster resilience and keep the child’s development “on track”) (see Chapter 27); and work as a collaborative team with the patients, the family, the school, and other providers to ensure coordination and continuity of culturally appropriate care.

Safety

Just as safety is a key issue to consider during the course of an assessment, it has no less a role in the initial phase of treatment planning. This is always a balance. In situations with the potential for child abuse or neglect, care needs to be taken to ensure the protection of the child as well as the rights of the child’s care takers in accordance the legal and ethical guidelines that are in place (see Chapters 19–22, 29, 30, and 49). The initiation of pharmacological treatment also requires that the family and the patient have a clear grasp of the risks and benefits. Often it is useful to delay the initiation of medications. The experience of going through an evaluation, learning about the disorder through psychoeducation, and giving voice to the child’s and family’s concerns can have a positive impact on the clinical picture. Simply having someone who understands the situation and is committed to working with the family and other practitioners can make a real difference. Likewise, given the increasing number of CBT interventions with proven efficacy, pharmacotherapy may not be the first agreed upon intervention (Leckman, 2013). Often the major problem is finding a clinician with the necessary skills and experience to provide the CBT with fidelity. However, once the joint decision is made to initiate medication, it is important for the child and family to “commit” to completing an adequate trial unless untoward side effects are clinically significant even after making any necessary adjustments in dosage or the timing of drug administration.

Build on strengths, foster resilience, and keep development “on track”

In our experience, supporting the positive elements of the child’s life is always an important part of the initial treatment planning. This is especially true if there are opportunities to build on the child’s talents and interests (music, sports activities, etc.). The child’s continued engagement in such activities provides something for him/her to be “proud of” and is a source of positive reinforcement. Physical exercise can also have a positive impact on the brain and there is some evidence to support its use across a range of conditions from ADHD to depressive mood (Petty *et al.*, 2009; Berwid & Halperin, 2012). It is also very important to emphasize with the patient and the parents the need to keep the child’s development “on track.” Almost invariably this means finding ways to continue the child’s life

with others outside the home. Withdrawal and isolation is a prescription for on-going self-doubt, low self-esteem, as well as problematic interactions in the home. For example, children with ADHD often have major difficulties with social acceptance and this can create a vicious cycle that involves a degree of social isolation, peer rejection, and an increased risk of being bullied (Murray-Close *et al.*, 2010; McQuade *et al.*, 2014). Depending on the child's developmental level, efforts to keep development on track may involve identifying opportunities for the child in question to interact with younger or older children rather than with their same-aged peers, for example, in religious groups or scouting or outdoor activities. In these contexts, the child with impaired social skills can interact with younger (as a mentor) or older peers (as a mentee). These new settings provide an opportunity for the child to be resilient in the face of continuing adversity (peer rejection, bullying, etc.) (see Chapter 27 and Panter-Brick & Leckman, 2013).

Team building with the child and the parents

Optional treatment planning and the willingness of the family to engage in treatment interventions depend on consensus building within the therapeutic alliance. This step can be problematic if the parents are in conflict and can easily provoke each other. In such instances, separate interactions with each parent may be of value in reinforcing the merits of a specific intervention as viewed from that parent's unique perspective. Encouraging acceptance of the realities of their lives and circumstances may permit a lessening of the anger and distress that continue to distract them from the needs of their child.

Interface with school personnel, pediatricians, and other practitioners

Often, the therapeutic team needs to involve other practitioners and professionals. Multiple examples come to mind. For example, autism spectrum disorders, and speech and language and other learning disorders, including ADHD, will often involve working with school personnel and other professionals and medical disciplines (see Chapters 51–55). In these complex situations, someone, besides a parent, needs to serve as the coordinator and convener as the child matures.

Cultural appropriateness

It is also important that clinicians do not lose sight of the unique cultural and religious background of the family during the treatment planning process. Attrition is a long-standing problem in mental health centers serving youth (Warnick *et al.*, 2012). Ethnicity is a consistent predictor of attrition particularly when the treatment provider is not from the same ethnic or religious background. Likewise, a family's ethnic and cultural background may influence their choice of various treatment alternatives. Although enduring therapeutic alliances are possible across ethnic and cultural backgrounds, a careful appraisal of the match between the mental health service providers and the family in question is encouraged.

Standards for Practice

Clinical practice must be performed under a variety of administrative, financial, and legal constraints. This chapter outlines what is needed to complete a psychiatric assessment. However, health services may not provide adequate time or resources and may require burdensome administrative tasks all of which compromise one's ability to complete a meaningful psychiatric assessment. In some instances, a short period of time may be sufficient, if the presenting problems are straight forward and not particularly worrisome, for example, uncomplicated bedwetting or parental "over-concern" about a preschool child's age-appropriate behavior toward siblings. However, when the presenting problems are substantial and context dependent, it is critical for the clinician to address each of the areas mentioned earlier in order to formulate a coherent narrative concerning the child's condition. Almost invariably this will require multiple sources of information and a degree of professional judgment. Clinicians must also act in accordance with the legal and ethical guidelines that are in place to ensure the safety of the child (see Chapters 19–22, 29, 30, and 49).

Approaches to assessment and treatment planning across the globe

Health-care systems vary widely across the world. Wonderfully, even in some Low and Middle Income countries, such as Brazil, health care is considered as a right not a privilege. On the other hand, in some of the wealthier countries, for example, the United States, marked disparities are still in place. In addition to access, the question of the quality of the services that are available is significant especially given the stigma associated with mental disorders and the shortage of well-trained practitioners (see Chapter 16). Often, the issues of access to and the availability of well-trained professionals means that the task of assessment falls to primary care clinicians, pediatricians, and to professionals in settings outside of medical centers, for example, school-based programs (see Chapters 42 and 48). In these contexts, the availability of expert consultants and the existence of sustainable programs to train professionals in school settings are an important focus for health care planning. Innovative approaches are needed to address these barriers and to improve access to care. Options to consider include the use of screening measures for detection of children at high risk coupled with a more complete second-stage diagnostic assessment and the use of nonspecialist workers in community and school settings for the delivery of psychosocial interventions (Patel *et al.*, 2013). One of the most promising emerging strategies is through the empowerment of existing human resources, for example, parents and other members of the extended families, through innovative technologies, such as mobile health, with the necessary skills for the detection and treatment of child mental disorders (see Chapter 16). The increasing use of electronic medical records, e-mail, and the social media is

also transforming aspects of referral and clinical assessments as well as treatment planning. For example, some interventions are now available online (Spence *et al.*, 2011). The internet is also an expanding source of information and misinformation increasingly used by parents as a guide to decision-making. Additionally, telemedicine is being increasingly used to provide mental health assessments and services at a distance (Grady & Nelson, 2011).

Conclusions

This chapter has sought to stress the importance of forming an alliance with the child and family, keeping in mind their cultural background and family milieu, their developmental status, and their perspective (as well as that of those around them) on their child's symptoms. The approach outlined requires multiple sources of information and clinical judgment; and sharing the information with the child and the family along with an honest appraisal of the child's prognosis. Treatment planning can then build on the child's strengths as a way to foster resilience and keep the child's development "on track." The child's response to treatment will indicate whether or not the therapeutic hypothesis was correct and what modifications are needed to ensure a path to recovery.

CHAPTER 33

Use of structured interviews, rating scales, and observational methods in clinical settings

Assessment procedures lie at the heart of healing professions. In this chapter we review procedures for selecting measures, summarize available measures, and discuss the importance of measurement in providing high quality clinical care.

Introduction

Systematic assessment is an essential part of any mental health evaluation. Assessment of youth differs fundamentally from that of adults. Unlike adults, children rarely initiate mental health contact. Typically, a parent, but sometimes a teacher or primary care doctor, has found the child's behavior problematic or noticed the child's distress. Hence, children are more likely to be referred for disruptive behavior than for anxiety, although anxiety is more prevalent. Most children coming for treatment have multiple disorders. Often, the most important or impairing problem is not the reason for seeking help. Moreover, youth assessment is complex. Younger children have limited insight and are poor informants about the timing, duration, and severity of their problems. Thus, assessment typically includes information from adults who know the child *and* from the child. These sources often disagree, sometimes because informants see youth in different settings or because informant characteristics influence their view of the child, but it is generally accepted that all information is diagnostically useful. Finally, youth are often reluctant reporters about embarrassing, distressing, or socially undesirable behaviors, even when directly questioned, a problem that might be addressed by automated measures (Bachman, 2003).

Treatment decisions should follow from a thorough initial assessment, ideally completed by a skilled clinician who interviews the child/adolescent and his/her parent(s), obtains a detailed history, collects information about social devel-

opment, and gathers information from third parties, such as teachers (see Chapter 32). The clinician also may review records and administer questionnaires. This initial assessment should include a "psychiatric review of systems" to identify possible diagnoses to be evaluated more thoroughly and ensure consideration of alternative diagnoses, as many symptoms (e.g., irritability, concentration problems) are shared across disorders. This ideal situation does not always occur. Instead, clinicians often make diagnostic decisions based on insufficient information ("premature closure") before considering information that might contradict initial hypotheses ("confirmation bias"). Clinicians also often neglect "rare" conditions and are influenced in diagnostic decision making by cases recently seen in clinics or discussed at meetings (the "availability heuristic"), and by the context in which the evaluation occurs (see discussion in Galanter & Patel, 2005). After the initial evaluation, it is important to undertake systematic (re)evaluations to identify conditions either missed or that arise during treatment.

Currently available assessment tools emerged after DSM-III (American Psychiatric Association, 1980) and expansion in child psychiatric research. By clearly delimited diagnostic criteria, DSM-III represented a radical new approach for diagnosis, which enhanced diagnostic reliability, improved communication, and facilitated the development of assessment instruments. Later revisions, culminating with DSM-5 in 2013 (American Psychiatric Association, 2013), extended this approach, with synergy between the DSM and ICD systems. Although the ICD classification code remains the standard for official morbidity and mortality reports, the DSM is often used to determine psychiatric diagnoses and create a medical record. Both systems include explicit criteria, which can be assessed with standardized instruments useful in both research and clinical settings.

During this period, rapid expansion in mental health research created a growing need for standardized assessments. Systematic errors plague routine clinical assessment, and research tools can aid clinical care. Historically, as clinicians faced increasing pressure to justify interventions, track progress, and report to third parties, clinical use of standard measures grew and yielded benefits. These included more comprehensive descriptions of patient populations, better monitoring of diagnostic changes over time, better tracking of treatment responses, and possible identification of homogeneous patient subgroups. Finally, educational value was shown; standard measures increase efficiency and help clinicians consider diagnoses they previously may have ignored.

Selecting measures

Purpose

The purpose of an assessment determines selection of measures, in terms of targeted symptoms and level of detail. For initial evaluations, broadband measures facilitate triage and identification of problems to be more intensively probed. Typically, an initial evaluation will assess material covered in comprehensive diagnostic interviews described later, supplemented by family factors and other social relationships. If the purpose of the assessment is to screen for a particular condition, one might choose a measure designed to identify that condition. For measuring severity or monitoring treatment, one would choose a measure that rates the severity of symptoms or the disorder.

Psychometrics

Reliability and validity should inform measurement selection. These properties are constrained by sampling and procedural factors. Measures tested in inpatient settings often work differently in outpatient settings. Measures which perform well in highly educated samples may perform less well in other samples.

Reliability refers to “repeatability” or “reproducibility,” the degree to which repeated administration yields the same results/answers. This can be quantified in several ways. “Internal reliability” or “internal consistency” quantifies the degree to which individual scale items measure one underlying construct (i.e., “repeat” each other). “Inter-rater reliability” quantifies the degree to which different raters generate the same result with the measure, which benefits from focused training. Thirty years ago, poor parent–child agreement was viewed as a “problem,” but this is now expected, and different informants’ perspectives are valued. A third type of reliability is test-retest, the degree to which repeated administration generates similar results in the absence of a change in the patient’s status. Good test-retest can only be documented by the readministration of measures, typically after a week to 10 days. It is necessary if an instrument is going to be used to measure change. Assessment of reliability of diagnostic interviews involves many challenges (see Shaffer *et al.*, 1999).

Validity refers to the degree to which an instrument actually measures the targeted construct. It is difficult to assess since

most mental health constructs lack accepted “gold standards” against which to compare the measure. As with reliability, there are many types of validity. “Face validity” involves mere inspection (or on the “face” of it), to evaluate if the measure seems to assess the relevant construct. “Concurrent validity” involves comparisons with other measures of the construct; “discriminate validity” involves determining if the measure differentiates cases with the targeted problem, relative to other, possibly similar problems. For screening, ability to identify cases with (sensitivity) or without (specificity) problems is of particular importance.

Practical considerations

In selecting measures, one set of practical issues includes the patient’s developmental level, sociocultural background, family literacy levels, and spoken language. The availability of private space, forms tested in the patient’s culture, and the length of time available are additional practical factors. For example, acquiring information before a face-to-face assessment can save time. Some measures require trained clinicians; others require even more specialized training; and still others can be administered on a computer. Other factors relate to ease of use, scoring, and interpretability, as well as history of use in similar settings. Diagnostic measures should reliably assess relevant disorder criteria at an appropriate level of specification. A final consideration is cost. Some instruments only can be used on a pay-per-administration cost; some require expensive training, others are “free” but may have hidden costs, related to staff time or questionable measurement properties.

Interviews

There are several interviews, which generate useful diagnostic information and differ in their structure. “Highly structured,” or “respondent-based,” interviews (RBI) require questions to be read *exactly as written* with few, predefined response options. The *respondent* must interpret questions. The Diagnostic Interview Schedule for Children (DISC, Shaffer *et al.*, 2000) is one widely used RBI. “Semistructured” or “interviewer-based” interviews (IBI) give the interviewer a pivotal role: she/he decides how to elicit and interpret information. Although IBIs may contain questions, these are “suggested”; the interviewer (re)words questions as appropriate and continues to ask questions until she/he decides the ratings. The Child and Adolescent Psychiatric Assessment (CAPA, Angold *et al.*, 1995) and versions of the Schedule for Affective Disorders and Schizophrenia for School Age Children (K-SADS, Kaufman *et al.*, 1997; Geller *et al.*, 2001) are examples of IBIs.

There are advantages and disadvantages to each approach. RBIs may be more standardized, are less expensive, and require far less training. However, they cannot address invalid responses and may miss atypical presentations. IBIs give interviewers the leeway to clarify discrepancies and use redundant questioning, but these require highly paid clinicians and extensive,

ongoing training to minimize interviewer variability and rater “drift.” The Development and Well-Being Assessment (DAWBA, Goodman *et al.*, 2000) combines these approaches. It includes an RBI comprising closed- and open-ended questions (responses are typed in) that is administered either by computer or interviewer with responses/results sent to an experienced clinical rater to make final diagnostic decisions.

Table 33.1 summarizes properties of commonly used interviews. Each yields DSM-IV (and for some ICD-10) diagnoses and will likely be revised for DSM-5. All are administered to parents and, depending on age of the youth, children separately, and information is combined using different procedures. Many have alternative versions for younger and older persons. For youth with multiple diagnoses, all can require hours to use. Each is used widely in research; few are routinely used in clinical services. The Anxiety Disorders Interview Schedule for Children (A-DIS-C, Silverman & Albano, 1996) has found use in specialized anxiety treatment centers, and the KSADS is used in some specialized mood clinics. The DAWBA and the DISC are both useful in settings where trained clinicians are not readily available. Although they cannot substitute for comprehensive clinical evaluation, they can greatly aid in screening and triage.

Scales

This section reviews data on various rating scales. This includes comprehensive scales and scales that assess more focused domains.

Comprehensive and broad-based scales

These scales are designed to efficiently assess diverse behavioral and emotional problems. Frequently utilized as screening instruments, broad-based scales present an efficient first assessment step. They may also be useful for public health and clinic administration review. We describe three widely used comprehensive and broad-based measures.

The Achenbach System of Empirically Based Assessment (ASEBA, Achenbach, 2009; www.aseba.org), which must be purchased, is the most widely used family of measures. This includes a Child Behavior Checklist for Ages 6–18 (CBCL/6–18), Teacher Report Form (TRF/6–18), Youth Self Report (YSR/11–18), Child Behavior Checklist for Ages 11/2–5 (CBCL/11/2–5) and Caretaker–Teacher Report Form (C–TRF), as well as forms for assessing adults. The ASEBA forms average 99–120 items to generate several syndrome scales with a strong research base in many languages and cultures (see Rescorla *et al.*, 2013).

The Behavioral Assessment System for Children (BASC-2, Reynolds & Kamphaus, 2004, www.pearsonclinical.com), another widely used cross-informant system that must be purchased, was designed to assess youth ages 4–18. BASC-2 forms contain 139–160 items. Inclusion of positive and adaptive adjustment is a distinctive feature of the BASC-2. Like the ASEBA, the BASC has broad- and narrowband scales,

with norms for general and clinical samples; it also has strong research support and validity scales to assess possible informant bias. The BASC-2 is available in Spanish, and psychometrics are good. For an in-depth comparison of ASEBA and BASC systems, see Rescorla (2009).

The Strength and Difficulties Questionnaire (SDQ, Goodman, 1997, 2001; Goodman & Scott, 1999), which is freely available (www.sdqinfo.org), was designed to be used as a brief behavioral screening tool for youth 2–17 years old that can be completed in 5 min. It contains just 25 items, has cross-informant forms, and yields five subscales. The SDQ has been translated into over 75 languages, possesses strong psychometrics (Hysing *et al.*, 2007), and correlates with CBCL scores (Goodman & Scott, 1999).

We limited our review to measures that are most widely used. Other measures include the Pediatric Symptom Checklist (PSC, Murphy & Jellinek, 1985), the Vanderbilt ADHD Rating Scales (discussed below) and the Child Symptom Inventories-4 (Gadow & Sprafkin, 1994). In addition, locally created checklists are often implemented in clinical settings as part of the intake to identify patient symptoms and probable diagnoses.

Anxiety and depression (also see Chapters 60 and 63)

Many measures are clinically useful. Because youth are considered the best source of information regarding their internal states, some measures began as “youth-only” measures. Informant agreement is typically low to moderate. Table 33.2 summarizes the properties of widely used measures with adequate psychometrics; many other measures are also available.

Anxiety

The Revised Children’s Manifest Anxiety Scale (RCMAS, Reynolds & Richmond, 1985), a downward extension of the adult Manifest Anxiety Scale (Taylor, 1953), must be purchased; it uses simple language to assess chronic, “manifest” anxiety as opposed to specific diagnoses in school-aged children, although it can also be used with older youth. The revised version, RCMAS-2 (Reynolds & Richmond, 2008), has a slightly different factor structure. While the psychometric properties are reasonable, the scale has been criticized for insufficient discriminant validity and lack of data on treatment-related change.

The State-Trait Anxiety Inventory for Children (STAIC; Spielberger *et al.*, 1973), another downward extension of an adult instrument, also must be purchased. It contains two 20-item self-rated scales to quantify “state” and “trait” anxiety and has no corresponding parent-informant version. The STAIC also has reasonable psychometrics and mixed discriminant validity with somewhat better specificity than sensitivity. The STAIC has been shown to be sensitive to change in transient and more general anxiety levels, making the state scale useful in assessing response to stress.

The Multidimensional Anxiety Scale for Children (MASC, March, 1997, March *et al.*, 1997; MASC-2, MASC-2-P, March, 2012) is another self-rated scale that must be purchased. It was

Table 33.1 Structured diagnostic interviews.

Instrument (Author)	Recommended age range	Time period assessed	Items/response format	Structure/organization	Interviews and training	Scoring/reports	Other information
Diagnostic Interview Schedule for Children, Version IV (DISC-IV) Shaffer <i>et al.</i> (2000)	6–17 years (6–8 parent only); young child and young adult versions available	Past year Past 4 weeks “Whole life” Voice & Present State version: past 4 weeks	All questions asked are coded usually “yes” or “no”; few open-ended questions; Responses entered into computer	RBI; questions read exactly as written; self-contained modules, can choose which diagnoses to assess; Few symptom skips within modules	Lay interviewer (2–3 days training CAPI) A-CASI: self-administered (half day training for administrator) Same or different interviewer for parent & youth	Scored by computer algorithm based on parent alone, youth alone, and combined parent and youth using “or rule”; symptom and criterion scales available	CAPI and A-CASI formats used Obtain information and interview from DISCGroup@nyspi.columbia.edu
The Development and Well-Being Assessment (DAWBA) Goodman <i>et al.</i> (2000)	5–17 years (5–10 parent only); teacher questionnaire	Current (but varies by diagnosis)	Most close-ended questions rated on a 3-point scale; for open-ended questions, responses typed verbatim with suggested follow-up probes if sparse answers	RBI; questions read as written, open-ended questions asked at end of each section or at end of interview; Clinician rater makes ratings based on information from all sources; Many symptom skips	Lay interviewer (1–3 days and “online” training available); Experienced clinician for final ratings; training varies by experience; Same or different interviewer for parent & youth	Preliminary scoring; “semi-automated” (“likelihood” and provisional diagnoses) by computer; Clinician assigns formal diagnoses based on clinical judgment	CAPI and CASI available; Obtain information and interview from http://www.dawba.com/
Missouri Assessment for Genetics Interview for Children (MAGIC) Reich and Todd (1997)	7–17 years; different child and adolescent versions	MAGIC: Lifetime (and also past month for mood) DICA: lifetime (not specified); current and past symptomatology	All questions asked are rated using categorical responses	MAGIC: RBI; with suggested follow up/clarifying probes; Some symptom skips	Lay interviewer (2–4 weeks of training); Same or different interviewer for parent & youth	Scored by computer algorithm for parent and youth separately	MAGIC: CAPI or CASI format; revision of a previous DICA version; Obtain information and MAGIC from author, Wendy4912@aol.com
Diagnostic Interview for Children and Adolescents-IV (DICA-IV) Reich (2000)			All questions asked are rated using categorical responses	DICA: RBI; usually CAPI or CASI; on paper some suggested follow-up probes (older versions); Some symptom skips	Lay interviewer (2–3 days); computerized (self) version; Same or different interviewer for parent & youth	Scored by computer algorithm for parent and youth separately	DICA: CAPI or CASI format; Obtain information and DICA from www.mhs.com
Child and Adolescent Psychiatric Assessment, Version 5.0 (CAPA) Angold <i>et al.</i> (1995)	8–17 years; young child and young adult versions available	Past 3 months	For most symptoms, separate scaled ratings of aspects of severity (intensity, frequency, duration, onset, resultant impairment)	IBI; extensive glossary defining symptoms and ratings; Few symptom skips	Lay interviewer (2–4 weeks training); Same or different interviewer for parent & youth	Scored by computer algorithm using “or rule”; utilizing “supervisor” ratings	Obtain information and interview from http://devepi.duhs.duke.edu/capa.html

Schedule for Affective Disorders and Schizophrenia for School-Age Children: Present and Lifetime (K-SADS-PL) Kaufman <i>et al.</i> (1997)	6–18 years	Current Past year without 2-month remission Lifetime: most severe	Most criteria/symptoms rated on 3-point scale, not present, subthreshold, threshold (definitions provided); some rated “yes” or “no”	IBI: interview starts with open-ended psychiatric/medical history; “Screen interview” determines which diagnoses to assess in “supplemental” modules; suggested questions; Many symptom skips	Clinician (3–4 days training); Same interviewer for parent & youth	DSM criteria rated by clinician based on all informants (including records); using clinician consensus ratings	DSM-5 version available; Obtain information and interview from joan.kaufman@yale.edu
Washington University Schedule for Affective Disorders and Schizophrenia for School-Age Children (WASH U K-SADS) Geller <i>et al.</i> (2001)	6–18 years	Current and lifetime onset, offset, and duration for most symptoms	Most criteria/symptoms rated on 7-point severity scale (from none to extremely profound), some on 4- or 5-point scale	IBI: interviewer starts with open-ended psychiatric/medical history suggested questions; Some symptom skips	Clinician (3–4 days training); Same or different interviewers for parent and youth	All symptoms occurring in same time period “count” towards diagnosis; DSM criteria rated by clinician based on all informants using “or” rule	Obtain information and interview from gellerb@wustl.edu
Anxiety Disorders Interview Schedule for Children (A-DIS-C) Silverman and Albano (1996)	6–17 years	Current and lifetime	Many questions rated “yes” or “no”, “Thermometers” used to obtain severity, fear/avoidance, distress, interference information; Interviewer makes clinician severity rating from 0 to 8 for each diagnosis	IBI: probes provided adapted by interviewer as appropriate; Some symptom skips	Clinician (1–3 days training; length depends on experience with child anxiety disorders); Same or different interviewers for parent and youth	Scored by clinician; Composite diagnoses from child & parent interviews derived by comparing responses. When symptom is endorsed on one version but not another both severity ratings and level of interference with functioning are considered.	Obtain information and interview from Oxford University Press

RBI = respondent-based interview.

IBI = interviewer-based interview.

A-CASI = audio-computer-assisted self-interview.

CASI = Computer-assisted personal interview.

CASI = Computer-assisted self interview.

“or rule” = criterion/symptom counted as positive if endorsed by parent or youth.

Table 33.2 Measures focusing on anxiety and depression.

<i>Anxiety: Questionnaires</i>									
<i>Instrument (Author)</i>	<i>Construct(s) assessed</i>	<i>Recommended age range</i>	<i>Time period assessed</i>	<i>Time to complete</i>	<i>Version: items (long/short)</i>	<i>Response format</i>	<i>Scoring/ reports</i>	<i>Computerized?</i>	<i>Any cost?</i>
Revised Children's Manifest Anxiety Scale: Second Edition (RCMAS-2) Reynolds and Richmond (2008)	Total anxiety; 3 subscales: physiological anxiety, worry, social anxiety; also assesses "defensiveness" (lie scale) and has "inconsistent reporting index"	6–19 years	Not specified; current; "true of you" trait	10–15 min	Youth: 49/10	Each item rated true or not true	Sum of items; total scores with cutoff points	Audio CD available for poor readers	Yes; WPS
State-Trait Anxiety Inventory for Children (STAIC, Spielberger et al. 1973)	State anxiety Trait anxiety	8–14 years	Current; "Right now" state and "Usually feel" trait	<20 min	Youth: 40	Each item rated on 3-point frequency scale: "hardly ever," "sometimes," "often"	Sum of items on each scale (norms available)	Computer software available for scoring	Yes; PAR
Multidimensional Anxiety Scale for Children (MASC) March et al. (1997)	Anxiety symptoms; 4 factors: physical symptoms, social anxiety, harm avoidance, separation anxiety (many DSM symptoms)	8–19 years	"Recently"	<15 min	Youth: 50/10 Parent: 50	Each item rated on 4-point scale ranging from "never true about me" to "often true about me"	Sum of items; T-score cutoffs for different severity levels and for "caseness"	Yes	Yes; MHS
Screen for Child Anxiety Related Emotional Disorders (SCARED) Birmaher et al. (1999)	DSM-IV anxiety disorder, including school avoidance	9–19 years	Last 3 months	10–15 min	Youth and Parent: 41/5	Each item rated on 3-point scale, "not true," "sometimes true," "very true"	Total scores with recommended cutoff points by age/gender	No	No; available at www.psychiatry.pitt.edu/research/tools-research/assessment-instruments
Spence Children's Anxiety Scale (SCAS) Spence (1998)	DSM-IV anxiety disorder	7–17 years	Not specified; current (items written in present tense)	10 min	Youth and Parent: 38	Each item rated on 4-point scale ranging from "never" to "always"; some items reverse scored	Sum of items; subscale scores for specific anxiety d/o given	Computer scoring	No; available at www.scaswebiste.com
Revised Child Anxiety and Depression Scales (RCADS) Chorpita et al. (2000)	DSM-IV anxiety disorder; depression	Grades 3–12	Not specified; current (items written in present tense)	10 min	Youth and Parent: 47	Each item comprises 4 statements of increasing intensity/severity (never to always)	Sum of items; T-score from appropriate grade level	Automated scoring online	No; available from authors, www.childfirst.ucla.edu

Hamilton Anxiety Rating Scale (HAM-A) Hamilton (1959)	Psychic anxiety (mental agitation and psychological distress) and somatic anxiety (physical complaints related to anxiety)	Children, adolescents, adults	Current (not specified)	10–15 min	Youth only: 14 items	Each item has 4 statements of increasing intensity/severity (none to severe)	Sum of items; suggested cutoffs for different severity levels and for "caseness"	No	No; public domain
Pediatric Anxiety Rating Scale (PARS) RUPP Anxiety Study Group (2002)	DSM-IV criteria and impairment for social phobia, separation anxiety, generalized anxiety disorder	6–17 years	Last week	<20 min	Youth and Parent: 50 symptom items; 7 global items	Each symptom item scored as present or absent (yes/no); global ratings rated by clinician on 7 dimensions of severity using a 6-point scale of increasing severity	Total score is sum of 7 global severity items	No	No; obtain information and scale from Mark Riddle, MD, mriddle1@jhmi.edu
<i>Depression: Questionnaires</i>									
Beck Depression Inventory-II (BDI-II) Beck et al. (1996)	All DSM-IV MDD ^a symptoms	13–80 years	Last 2 weeks	5–10 min	Youth: 21	Each item comprises 4 statements of increasing intensity/severity	Sum of items; suggested cutoffs for different severity levels and for "caseness"	Yes	Yes; PsychCorp
Children's Depression Inventory 2 (CDI 2) Kovacs (2010)	Most DSM-IV MDD ^a symptoms Other associated symptoms	7–17 years	Last 2 weeks	5–15 min	Youth: 28/12 Teacher: 12 Parent: 17/12	Each item comprises 3 statements of increasing severity/intensity; (some items reverse scored)	Sum of items; corresponding T-score, suggested cutoffs for different severity levels and for "caseness"	Yes	Yes; MHS
Center for Epidemiological Studies-Depression Scale (CES-D) Radloff (1977)	Some DSM-IV MDD ^a symptoms	CES-D: 12–96 years CES-DC: 6–17 years	Last week	5–10 min	Youth: 20	Each item rated on 4 point scale of frequency, "rarely or none of the time" to "most or all of the time"; (some items reverse scored)	Sum of items; suggested cutoffs for different severity levels and for "caseness"	Yes	No; available online on various websites
Center for Epidemiological Studies-Depression Scale for Children (CES-DC) Weissman et al. (1980)

<i>Anxiety: Questionnaires</i>									
<i>Instrument (Author)</i>	<i>Construct(s) assessed</i>	<i>Recommended age range</i>	<i>Time period assessed</i>	<i>Time to complete</i>	<i>Version: items (long/short)</i>	<i>Response format</i>	<i>Scoring/reports</i>	<i>Computerized?</i>	<i>Any cost?</i>
Mood and Feelings Questionnaire (MFQ) Costello <i>et al.</i> (1991)	Long: All DSM-IV MDD symptoms; other associated symptoms Short: Some DSM-IV symptoms	8–18 years; modified for 6–12 years	Last 2 weeks	5–10 min	Youth: 33/13 (6–12 years); 14 Parent: 34/13	Each item rated on 3-point scale, “true,” “sometimes true,” “not true”	Sum of items; no prescribed cutoffs (up to user)	No	No; obtain information and scale from: http://devepi.duhs.duke.edu/MFQ.html
Quick Inventory of Depressive Symptomatology (QIDS) Rush <i>et al.</i> (2003)	All DSM-IV MDD symptoms	QIDS: 18–75 years QIDS-A: 12–17 years	Last week	5–8 min	QIDS: Youth and Clinician: 16 QIDS-A: Youth, Parent, and Clinician: 17	Each item comprises 4 statements of increasing severity/intensity	Sum of highest score items; suggested cutoffs for different severity levels and for “caseness”	No	No; QIDS: < www.ids-qids.org/ > QIDS-A: < graham.emsle@utsouthwestern.edu >
Quick Inventory of Depressive Symptomatology—Adolescent (QIDS-A) Moore <i>et al.</i> (2007)									
Reynolds Adolescent Depression Scale, Second Edition (RAD5-2) Reynolds (2002)	Long/Short: Most DSM-IV MDD symptoms; Other associated symptoms	RADS: 11–20 years RCDS: 7–13 years	RADS: current; not specified RCDS: Last 2 weeks	RADS: 5–10 min RCDS: 10–15 min	RADS: Youth: 30/11 RCDS: Youth: 30/10	Each item rated on 4-point scale of frequency from “almost never” to “all the time”; (some items reverse scored); RCDS-2 includes additional global item	Sum of items; corresponding T-score, suggested cutoffs for different severity levels and for “caseness”	No	Yes; PAR
Reynolds Child Depression Scale, Second Edition (RCDS-2) Reynolds (2010)									
<i>Depression: clinician-administered measures</i>									
<i>Instrument (Author)</i>	<i>Construct(s) assessed</i>	<i>Age range</i>	<i>Time period assessed</i>	<i>Time to complete</i>	<i>Informant: items (long/short)</i>	<i>Response format</i>	<i>Scoring/reports</i>	<i>Computerized?</i>	<i>Any cost?</i>
Hamilton Rating Scale for Depression (HAM-D) Hamilton (1960), Warren (1997)	Most DSM-IV MDD symptoms	13+ years	Current (not specified)	5–10 min	Youth only: 17, 19, 21 (different versions)	Each item rated on 5-point or 3-point scale with increasing symptom severity	Sum of first 17 items; cutoffs for different severity levels and for “caseness”	Yes	No; public domain
Children's Depression Rating Scale-Revised (CDRS-R) Poznanski and Mokros (1996)	All DSM-IV MDD symptoms	6–12 years (often used with adolescents)	Current (not specified)	20–30 min	Youth and Parent and Other: 17 items	Each item rated on 5-point or 7-point scale with increasing symptom severity	Sum of items; T-scores, cutoffs for probable diagnosis	No	Yes; WPS

^aMDD = Major depressive disorder.

developed on the basis of research to improve upon earlier anxiety scales, such as the RCMAS and STAIC. The MASC has been translated into over 15 languages. The psychometrics properties of this scale are good, and the measure is sensitive to treatment. The current version, MASC-2, contains 50 items assessing features of DSM diagnoses and includes a parent form. Less is known about the MASC-2 and the parent version, but initial results are promising.

The Screen for Child Anxiety Related Emotional States (SCARED, Birmaher *et al.*, 1999) is a freely-available self-rated scale also developed to improve upon earlier scales. Like the MASC, it assesses features of DSM diagnoses, has self- and parent-rated versions, and has been translated into multiple languages. It has both long, 41-item, and short, 5-item versions. The psychometrics are good, and the measure is sensitive to treatment effects.

The Spence Children's Anxiety Scale (SCAS, Spence, 1998) is a freely available youth-completed instrument with corresponding parent (Nauta *et al.*, 2004) and preschool versions (Spence *et al.*, 2001). The psychometrics are good, the scale has been translated into several languages, and it is sensitive to treatment effects. The Revised Children's Anxiety and Depression Scale (RCADS, Chorpita *et al.*, 2000), another freely available scale, closely resembles the SCAS, and also assesses depression, which is useful in many settings. The scale's psychometric properties are good, and the scale has been translated into several languages.

The Hamilton Anxiety Rating Scale (HAM-A, HARS, Hamilton, 1959) is a freely available clinician-rated measure that quantifies the severity of global anxiety by requiring clinicians to make five-point ratings of multiple physiologic and psychic-anxiety symptoms. No guidelines inform clinicians on procedures for generating scores. The HAM-A has been used with adolescents in addition to adults, with whom it is a widely used outcome measure. The measure requires extensive training and tends to focus heavily on somatic symptoms.

The Pediatric Anxiety Rating Scale (PARS, RUPP Anxiety Study Group, 2002) is another freely available clinician-rated measure. It targets symptoms not covered adequately by the HAM-A or HARS, and it is modeled on the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS, Scahill *et al.*, 1997) (see subsequent text). After a review of symptoms, clinicians rate severity on seven dimensions using a six-point scale. The psychometrics are good, and the scale is sensitive to treatment effects. However, administration is lengthy, and it requires extensive training.

Depression

The Beck Depression Inventory (BDI-II, Beck *et al.*, 1996) is a widely used self-report scale that must be purchased and maps onto DSM criteria. This easy-to-use scale has good psychometrics, is sensitive to treatment effects (at least among adults), and it includes an item about suicidality. Modeled after the BDI, the Children's Depression Inventory (CDI-2, Kovacs, 2010) is widely

used in 6-to-17 year-olds. While the psychometrics generally are good and the scale is sensitive to treatment effects, results are mixed in terms of distinguishing depression from other disorders. Although the scale is widely used for screening, sensitivity may be poor. The CDI has been translated into several languages. It also includes an item about suicidality.

The Center for Epidemiological Studies Depression Scale (CES-D, Radloff, 1977) is a freely available self-report depression scale developed for use in adult epidemiological studies. However, it does not cover suicidality and many DSM criteria. The Center for Epidemiological Studies Depression Scale for Children (CES-DC) is a version for youth, without a "parent-informant" version. Both are available in several languages. Criticisms of these scales focus on the incomplete coverage of depression items and nonspecificity for depression.

The Mood and Feelings Questionnaire (MFQ, Costello *et al.*, 1991) is a freely available self-report depression scale that allows rapid evaluation. A parallel parent report exists, as do short forms. The psychometrics are strong, and discriminability for depression appears better than for other self-report measures.

The Quick Inventory of Depressive Symptomatology (QIDS Rush *et al.*, 2003) and QIDS-A (adapted for adolescents, Moore *et al.*, 2007) are short forms of the Inventory of Depressive Symptomatology (IDS, Rush *et al.*, 1996). These freely available forms assess symptom criteria of Major Depressive Episode and are well suited for tracking treatment response. Both self- and clinician-rated versions exist, as well as a structured interview guide. The QIDS is widely translated, has strong psychometrics and has been adapted specifically for use with children and adolescents.

The Reynolds Adolescent Depression Scale, Second Edition (RADSD-2) ("About Myself") (Reynolds, 2002) and the corresponding Reynolds Child Depression Scale, Second Edition (RCDS-2) ("About Me") (Reynolds, 2010) are two scales that must be purchased and can be used for screening, research, and monitoring treatment. There are no corresponding parent forms. The psychometrics are strong, norms are available, and the scales are easy to use.

The Hamilton Rating Scale for Depression (HDRS or HAM-D, Hamilton, 1960) is a freely available, clinician-rated measure that has been widely used in treatment studies of adult depression. Several versions exist, with the HAM-D used most widely (Guy, 1976). The measure does not cover all depressive items, since it was developed long before DSM-III, and it has been criticized for its psychometrics (Bagby *et al.*, 2004). Nevertheless, it has played an important role in evaluating many treatments for depression over the past three decades.

Modeled after the HAM-D, the Children's Depression Rating Scale—Revised (CDRS-R, Poznanski & Mokros, 1996) is a clinician-rated measure that must be purchased. The scale is completed after the clinician interviews the patient and a parental informant. For youth, the CDRS-R is the measure of choice for most treatment outcome studies. The CDRS has been translated into several languages. The psychometrics are

generally strong, provided that clinicians are properly trained and monitored, and the scale assesses suicidality. Norms are available, but are not typically used. Like the HAM-D, in typical clinical settings the CDRS-R might best be used as a measure with children who have been determined to or suspected of having a depressive illness to quantify severity and track change.

Disorders of attention, impulsivity, hyperactivity and disruptive behavior (also see Chapters 55 and 65)

There are many scales to assess disruptive behaviors. In contrast to mood and anxiety symptoms, disruptive behaviors are more readily observable, leading parents and teachers to provide highly valued information (Loeber *et al.*, 1990). Both should be used to generate a comprehensive assessment, supplemented by children's reports, particularly for covert behaviors, such as lying or stealing, although children may conceal such behaviors from the clinician. Table 33.3 summarizes properties of the broadest, most widely used measures with adequate psychometric properties, while chapter text highlights key features.

There are several widely used scales developed by C. Keith Conners and colleagues to assess attention deficit hyperactivity disorder (ADHD) and disruptive disorders. The current version, which must be purchased, is the Conner 3 (third edition). It has parent, teacher, and self-rated forms with good psychometrics, especially for ADHD and disruptive behaviors. It has been used to track treatment and screen for ADHD.

The Swanson, Nolan, and Pelham Rating Scale, Fourth Edition (SNAP-IV, Swanson *et al.*, 2001) assesses DSM ADHD, oppositional-defiant disorder (ODD) and related criteria via parent and teacher reports. There is no self-report. This freely available widely-used scale has strong psychometrics, especially for ADHD, and is sensitive to treatment effects. The Strengths and Weaknesses of ADHD Symptoms and Normal Behavior (SWAN, Swanson *et al.*, 2006) is another freely available scale developed to address concerns about the SNAP-IV's exclusive focus on pathological behaviors. Unlike those for the SNAP-IV, SWAN items are rated using a scale ranging from "far below average" to "far above average" to reflect both weaknesses and strengths. The SWAN is easy to use and is available in several languages, but few treatment studies have used the SWAN.

The Vanderbilt ADHD Rating Scales (VARS, Wolraich *et al.*, 1998, 2003) are more recent DSM-IV focused parent and teacher reports that assess for ADHD, ODD, and conduct disorder, though they also have features similar to comprehensive measures. The scales have good psychometrics and have been translated into several languages. English versions can be found on various Internet sites (e.g., www.childrenshospital.vanderbilt.org/services.php?mid=5734). One advantage of the VARS is the ability to assess comorbid externalizing and internalizing symptoms.

The Eyberg Child Behavior Inventory (ECBI, Eyberg & Pincus, 1999) is a parent report scale, widely used in both treatment studies and clinical settings, for assessing symptoms

of disruptive behavior disorders. This easy-to-use scale must be purchased, is available in many languages, and has a corresponding teacher scale, the Sutter-Eyberg Student Behavior Inventory. The scales have been normed.

The Overt Aggression Scale (OAS, Yudofsky *et al.*, 1986) and Modified Overt Aggression Scale (Sorgi *et al.*, 1991) are both freely available (for OAS see, www.bcm.edu/departments/psychiatry-and-behavioral-sciences/index.cfm?pmid=3896; for MOAS see www.thereachinstitute.org/files/documents/moas.pdf). These scales track severity in real time, with the OAS focusing on behavior present "in the moment," and the MOAS including ratings for the past week. An observer rates the presence of various aggressive events during a specific time interval. While the scale has novel features, limited psychometric data are available.

The Children's Aggression Scale (CAS, Halperin *et al.*, 2002, 2003), which must be purchased, was developed to focus specifically on aggression. It has parent and teacher scales that weight items to account for severity. The scale has strong psychometrics and is normed.

The Buss-Durkee Hostility Inventory (BDHI, Buss *et al.*, 2003) is a self-report scale that is unique for its focus on hostility. Developed for college students, the scale was modified for youth. The original version has reasonable psychometrics. However, many versions exist and the psychometrics have not been examined for all of them. The scale is available in several languages.

Scales for other specific disorders

Part IV of this volume comprises chapters on specific syndromes, with discussions of assessment measures. Here, we review some commonly used measures.

For autism spectrum disorders (see Chapter 51), there are several good screening measures, including the Social Communication Questionnaire (SCQ, Rutter *et al.*, 2003a, b), the Autism Spectrum Screening Questionnaire (ASSQ, Ehlers *et al.*, 1999), the Childhood Autism Rating Scale, Second Edition (CARS 2, Schopler *et al.*, 2010) and, for very young children, the Modified Checklist for Autism in Toddlers (M-CHAT, Robins *et al.*, 1999). The Autism Diagnostic Interview—Revised (ADI-R, Rutter *et al.*, 2003a, b) and the Autism Diagnostic Observation Schedule (ADOS-2) discussed subsequently are state-of-the-art diagnostic measures.

For tic disorders (see Chapter 56), the clinician-rated Yale Global Tic Severity Scale (YGTSS, Leckman *et al.*, 1989) quantifies overall tic severity in the week preceding evaluation. This is the measure of choice for treatment outcome studies, is a useful aid for clinicians, and is freely available. The Premonitory Urge for Tics Scale (PUTS; Woods *et al.*, 2005) is a brief self-report measure, which can be useful when using behavioral interventions to treat these disorders.

For obsessive compulsive disorder (see Chapter 61), the Leyton Obsessional Inventory-Child Version (LOI-CV; Berg *et al.*, 1986) has utility as a screen and good psychometric

Table 33.3 Measures focusing on behavioral and disruptive symptoms.

Instrument (Author)	Construct(s) assessed	Age range	Time period assessed	Time to complete	Version: items (long/short)	Items/response format	Scoring/ reports	Computerized?	Any cost?
Conners Third Edition (Conners 3) (Conners (2008)	DSM-IV criteria, assesses ADHD, CD, ODD, learning problems, executive functioning, aggression, peer/family relations in home, social, school settings.	6–18 years (self-report)	Last month	10–20 min	Youth: 99/41 Parent: 110/45 Teacher: 115/41	Each item rated on a 4-point scale from “not true at all/never” to “very much true/very often”	Sum of items with suggested cutoffs and percentages with T score for different severity levels	Yes	Yes; MHS
Swanson, Nolan, and Pelham Rating Scale, Fourth Edition (SNAP-IV) (Swanson et al. (2001)	DSM-IV ADHD, ODD, other related diagnoses	6–18 years	User choice	10 min	Parent and Teacher: 26/90	Each item rated on 4-point scale of frequency from “not at all” to “very much”	Sum of items; cutoffs percentages for caseness	No	No; www.ADHD.net
Strengths and Weaknesses of ADHD symptoms and Normal behavior scale (SWAN) (Swanson (2006)	DSM-IV ADHD; adaptive and impaired ends of ADHD symptom dimensions	6–18 years	Last 6 months	5 min	Parent and Teacher: 18	Each item rated on a 7-point scale with “average behavior” scored in the middle and “far below average” and “far above average” at the extremes	Sum of items; cutoffs percentages for caseness	No	No; www.ADHD.net
Vanderbilt ADHD Rating Scales (VARS) (Wolraich (1998, 2003)	DSM-IV; inattention, hyperactivity/impulsivity, oppositional-defiant/conduct disorder, anxiety/depression, academic and classroom behavioral performance	Kindergarten to fifth grade	Current	10 min	Parent: 55 Teacher: 43	Each item rated on a 4-point scale of increasing frequency from “never” to “very often”; performance section rated on a 5-point scale of increasing performance from “problematic” to “above average”	Suggested score of select items required for “caseness”	No	No; www.childrenshospital.vanderbilt.org/services.php?mid=5734

(continued overleaf)

Table 33.3 (continued)

Instrument (Author)	Construct(s) assessed	Age range	Time period assessed	Time to complete	Version: items (long/short)	Items/response format	Scoring/ reports	Compu- terized?	Any cost?
Eyberg Child Behavior Inventory (ECBI) Eyberg and Pincus (1999)	Conduct problems; intensity scale; problem scale	2–16 years	Current	5 min	Parent: 36	Each item on the intensity scale is rated on a 7-point scale of increasing frequency from “never” to “always”; problem scale asks parents to indicate “yes” or “no” to whether behavior is a problem	Sum of items, weighted depending on severity; suggested cutoffs with T-score for clinical range of problems	No	Yes; PAR, Inc.
Overt Aggression Scale (OAS) Yudofsky et al. (1986)	Verbal aggression, physical aggression against objects, physical aggression against self, physical aggression against other people, staff intervention	6–17 years, adults	Last 24 hours	5 min	Clinician: 7	Each behavior item has 4 levels of severity; type of staff intervention and severity of intervention are also ranked	Sum of items, weighted depending on severity; suggested cutoffs with T-score for clinical range of problems	No	No; https://www.bcm.edu/departments/psychiatry-and-behavioral-sciences/index.cfm?pmid=3896
Children's Aggression Scale (CAS) Halperin et al. (2002)	Frequency/severity of aggressive acts, distinct from oppositional and defiant behaviors, within and outside of home setting	5–18 years	Last year	10–15 min	Parent: 33 Teacher: 23	Each item is scored on a 5-point scale with increasing frequency/severity of symptom from “never” to “most days”	Sum of items, weighted depending on severity; suggested cutoffs and percentages with T-score for different severity levels	Yes	Yes; PAR
Buss-Durkee Hostility Inventory (BDHI) Aggression Questionnaire (AQ) Buss and Warren (2000)	Physical aggression, hostility, verbal aggression, anger, indirect aggression	9–88 years	Not specified	10 min	Youth: 34	Each item rated on 5-point scale from “not at all like me” to “completely like me”	Sum of items; corresponding T-score, suggested cutoffs for different severity levels and for “caseness”	Yes	Yes; WPS

properties. The Children's Yale-Brown Obsessive-Compulsive Scale (CY-BOCS, Scahill *et al.*, 1997), a clinician-rated measure, is the measure of choice for tracking treatment outcome.

Two frequently used self-completed measures to screen for symptoms of traumatic stress (see Chapter 59) are the Children's Revised Impact of Event Scale (CRIES, Smith *et al.*, 2003; Yule, 1997) and UCLA Post Traumatic Stress Disorder (PTSD) Reaction Index (USLA-PTSD-RI) Steinberg & Brymer, 2008; Steinberg *et al.*, 2013). The Children's PTSD Inventory (CPTSDI, Saigh *et al.*, 2000) is a clinician-rated measure. The Child PTSD Symptom Scale (CPSS, Foa *et al.*, 2001) can be used as an interview measure by a clinician or can be self-completed. Except for the CRIES, all can be used to assess PTSD as defined by DSM-IV. For eating disorders (see Chapter 71) both the Eating Attitudes Test (EAT-26, Garner *et al.*, 1982) and the Eating Disorder Exam Questionnaire (EDE-Q, Fairburn & Beglin, 1994) may be used for screening.

For bipolar disorder (see Chapter 62), a problematic diagnosis for youth, there is no consensus on a good screening instrument (see Youngstrom *et al.*, 2001; Gracious *et al.*, 2002; Pavuluri *et al.*, 2006; Wagner *et al.*, 2006). Potentially useful clinician-rated measures include the Young Mania Rating Scale (Young *et al.*, 1978) and the K-SADS Mania Rating Scale (Axelson *et al.*, 2003).

Finally, there are many freely available, psychometrically strong screens for substance use (see Chapter 66). These include the CRAFFT Screen tool (Knight *et al.*, 2002), the Adolescent Alcohol and Drug Involvement Scale (AADIS, Moberg, 2000); the CAGE (for alcohol problems) (Ewing, 1984), the Drug Abuse Screening Test for Adolescents (DAST-A, Skinner, 1982; Martino *et al.*, 2000) and the Michigan Alcoholism Screening Test (MAST, Selzer, 1971).

Impairment and functioning

This section focuses on well-known measures with adequate psychometrics. Measures not reviewed include those used primarily in service delivery systems, such as the Child and Adolescent Functional Assessment Scale (CAFAS, Hodges, 2000a, b) and the Child and Adolescent Needs and Strengths-Mental Health (CANS-MH, Lyons *et al.*, 1999), or that are less widely used outside a pure research setting, for example, the Social Adjustment Inventory for Children (John, *et al.*, 1987). In addition, the diagnostic interviews and the omnibus measures reviewed earlier, each include some assessment of impairment.

The Children's Global Assessment Scale (CGAS, Shaffer *et al.*, 1983) is a global, one-item rating scale that asks clinicians to rate the child's most impaired level of functioning from 1 (needs constant supervision) to 100 (superior functioning) within the time period the user selects (typically 1 month) based on all available information. This easy and widely used measure has good psychometrics, though the scale has been criticized for subjective descriptions. A parent-rated version (Bird, 1999) is also available. The scales are available in many languages. Both scales are available at no charge from the authors (DISCGroup@nyspi.columbia.edu).

The Columbia Impairment Scale (CIS, Bird *et al.*, 1993; Bird, 1999) is a global scale completed by parents of children ages 6–17 or to children themselves ages 9 and older. The Brief Impairment Scale (BIS, Bird *et al.*, 2005) contains 10 additional items and evaluates three domains of functioning. These scales have an advantage over the CGAS in that they are respondent based. Both are psychometrically sound; however, neither has been normed or used as often as the CGAS. Both are free from the authors (DISCGroup@nyspi.columbia.edu)

The Vineland Adaptive Behavior Scales, Second Edition (Vineland-II, Sparrow *et al.*, 1984) must be purchased (see www.pearsonclinical.com) and have been widely used in both clinical and research settings, particularly for children with developmental delays, ADHD, or on the "autism spectrum." The Vineland-II covers most of the lifespan, has multiple versions, is useful in various settings, with norms and good psychometrics, and effectively tracks children's developmental progress.

Observations

Observational measures record behaviors at the time they occur. Observations assess children with limited communication and may be less affected by respondent biases than teacher or parent scales. Validity may be affected by both type (e.g., naturalistic versus structured) and setting (e.g., home, school, or clinic) (Gardner, 2000). Because cognitive and internal states must be inferred by physical manifestations, observational methodologies complement but do not replace other assessments (Gardner, 2000).

Some measures directly assess environmental triggers, reinforcers, and factors that maintain behavior, as may occur during social interactions. Some schemes are explicitly designed to "press" for behaviors that may not occur without a trigger, like asking a child to clean up after play or separate from a caregiver. Concrete environmental factors can also be assessed. The Dyadic Parent Child Interaction Coding System (DPICS), the observational assessment in Parent Child Interaction Therapy (PCIT), has proved useful in treating disruptive behaviors.

Observational measures require significant time investments to master coding. Observational assessments can be made in naturalistic, behavioral analog, and standardized settings, usually attempting to capture settings where problematic behaviors typically occur (Skinner *et al.*, 2000). Naturalistic observations have the advantage of ecological validity but may fail to capture relevant, infrequently occurring behavior. Analog observation methods mimic real-life conditions in a clinic setting, sometimes through enactments. For example, a parent and child may be asked to engage in a play activity, where the parent is asked to direct the child to clean up toys. Analog methods facilitate controlled opportunities to elicit low-frequency behaviors (Mash & Foster, 2001). With standardized diagnostic observations, the examiner directly participates as an observer and as a confederate in a systematic protocol that elicits behaviors relevant

to a specific diagnosis. The examiner follows a protocol that provides contextual “presses” for specific behaviors.

Below we highlight features of common observational systems.

The Autism Diagnostic Observation Schedule (ADOS-2) involves standardized interactive activities introduced by the clinician in an effort to elicit social interactions and other settings where autism symptoms manifest (Lord *et al.*, 2000, 2001). The ADOS-2 has considerable empirical support and is recommended as a best-practice guideline (National Research Council, 2001). The psychometrics of the ADOS-2 are adequate, provided the user has been properly trained. The ADOS-2 is utilized in conjunction with a parent interview (e.g., the Autism Diagnostic Interview, Revised) and developmental history report. The ADOS-2 is standardized in terms of materials and activities, requiring hierarchical sequences of presses or prompts. It takes 40–60 min to administer, during which time the observer continuously takes qualitative notes. Afterward, the behaviors are coded and entered into an algorithm to rate features of an autism spectrum disorder.

The Disruptive Behavior Diagnostic Observation Schedule (DB-DOS) is a 50-min structured observation method that utilizes behavioral presses. It combines both examiner and parent behavioral observation with parallel sets of presses. Two core domains are assessed: problems in behavioral regulation and problems in anger modulation. The DB-DOS coding system attempts to distinguish normative from clinically concerning misbehavior through clinician judgment. Like the ADOS, the psychometrics are adequate with appropriate training.

The Direct Observation Form (DOF, Achenbach, 1986; Achenbach & Rescorla, 2001), like other components of the ASEBA system, must be purchased. The DOF obtains ratings of problem behaviors and on-task behavior through direct observations of a child over 10 min periods in the classroom and during group activities (such as recess). Because children’s behavior may vary across occasions, three to six separate observations are recommended. The DOF is normed and has adequate psychometrics. Clinical utility is a notable strength.

The Student Observation System (SOS) is part of the BASC-2 system, so must be purchased. SOS is designed to assess both adaptive and maladaptive classroom behaviors during a 30-min observation session, typically repeated across 3 or 4 days in different classrooms. The system utilizes a time-sampling method, which has observers recoding student and teacher behavior in 30-s intervals. Student adaptive and maladaptive behaviors are recorded in the last 3 s of the observation. The BASC-2 system also offers a Portable Observation Program (POP), which allows the observer to utilize the SOS template or design their own template for classroom observations on their laptop. The BASC-2 SOS has limited published data regarding psychometric properties.

The Coding Interactive Behavior (CIB, Feldman, 1998) system is a measure that assesses the quality of dyadic interaction with versions for newborns, infants, children, adolescents, and adults.

The CIB has good psychometrics, has been validated, and is sensitive to important sociocultural parameters (Feldman 2003; Feldman & Eidelman, 2007). Training is offered by authors of the measure and qualified trainers with annual monitoring to address rater drift.

Implementing standardized assessments in clinical settings

Clinical use of standardized measures presents several challenges. Many clinicians trust their own clinical judgment and impressions and see little need to change their usual practice; some may already feel overwhelmed by paperwork and record keeping and see little value in adding to that load; and some may worry that their performance will come into question should they not agree with the findings of standard tools. Clinicians may think that using questionnaires may be off-putting to patients and families and will interfere with the clinical process—although research suggests that this is not usually a problem—and that introducing standard diagnostic interviews will constrain their inquiry. Thus, it is important to recognize potential biases, understand the uses of standardized measures, and educate clinical staff about advantages and disadvantages of each measure. For example, if introducing a diagnostic interview, one can point out that structure mimics a typical clinical evaluation; if using the DISC, DAWBA, ASEBA, or BASC systems, efficiency might be emphasized. When using all such measures, it is important to systematically consider procedures for generating the most useful information from each measure. Standardized measures provide efficient assessment structures that are best viewed as aids in the assessment process, which increase consistency. They do not substitute for a comprehensive clinical evaluation, described in Chapter 32.

Conclusion

Standardized measures can be used to assist the clinical process. They include a range of diagnostic interviews, comprehensive questionnaires, more targeted scales, and structured clinical observation schedules. Evidence-based assessments require both effective measurement and sound clinical judgment, with standardized measures aiding, but not replacing clinical skills in assessment.

Psychological assessment in the clinical context

Tony Charman¹, Jane Hood² and Patricia Howlin¹

¹Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Introduction

Psychological assessment of young people may be needed for many reasons. Usually, the assessment will be a response to concerns that an adult has about the young person. The assessment domains that need to be considered are wide and, given the well-established link between developmental, cognitive or learning difficulties and emotional and behavioral difficulties, most assessments should consider both development and behavior, alongside the child's emotional well-being. The family, home, and school environment should also be considered. Psychological assessment will often include some direct assessment of the child's functioning, observations of the child, interviews with parents and, where appropriate, relevant information from school. Depending on the setting, both formal and informal measurement and testing may be required. Psychological assessment should adopt a "scientist-practitioner" model whereby a theory-driven assessment generates and tests hypotheses. Thus, the assessment provides a framework for difficulties to be targeted for remediation (see Figure 34.1).

Many professionals will use aspects of psychological assessments. In communities with well-developed professional structures these will typically include clinical (health service) and educational (school) psychologists as well as other professionals. In such communities, the most common service settings in which psychological assessments take place are child psychiatric services, child development/pediatric services, education settings and child health settings, as well as some specialist medical settings (e.g., neurology, genetic counseling services). Other practitioners will also benefit from material covered in this chapter, which also apply to many non-psychological practitioners in low- and middle-income countries where professional training in psychology is less well established.

This chapter first describes broad principles underpinning assessments. We then summarize information on commonly-

used norm-referenced measures. We conclude by discussing how psychological assessment informs interventions.

Psychological assessment within the broader context

Later in the chapter, we describe tests of intelligence. However, psychological assessment is much more than intelligence testing! Although psychometric tests serve important functions, children rarely are referred solely to measure their intelligence quotient (IQ). Psychological assessment is more often requested because of wider concerns—Why has a child suddenly become withdrawn and sullen? Why is she/he having so many problems within the classroom? Why is she/he falling behind the rest of the class, or is unable to relate to peers? The primary purpose of psychological assessment is to gain insight into a young person's behavioral, mental-health, educational, or learning difficulties, by developing and testing formulations about underlying influences and thus guiding interventions. It involves many methods, informal as well as formal, based in the context of the younger person's family and other key environments (e.g., school, peer group, and wider society). In other words, psychological assessment is not merely the administration of tests but involves the identification of key clinical issues pertaining to each *individual* case; the formulation of clinical issues into testable hypotheses; and the recurrent implementation and evaluation of hypothesis-driven interventions (see Chapter 32).

Informal and semi-formal clinical assessments

Pre-assessment assessments

Individual clinical assessments are costly in terms of both time and personnel, but appropriate use of pre-existing information

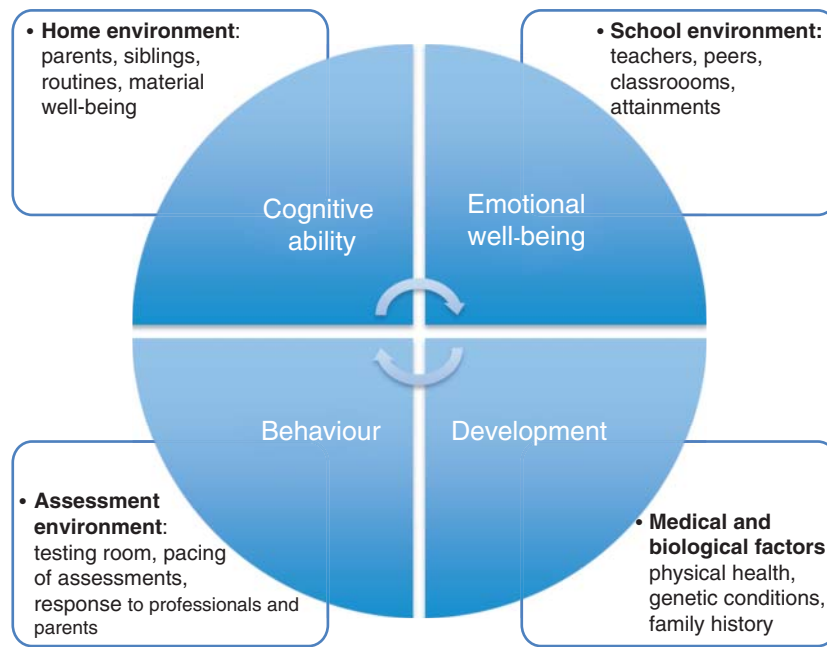

Figure 34.1 Child and environmental factors relevant to psychological assessment.

can greatly improve assessment efficiency and effectiveness. Detailed referral information can provide extremely helpful history, which can ensure availability of necessary clinical expertise and relevant individuals to inform the assessment. Information from parents, schools, and other services also can focus the assessment on the most pressing needs of the child and family. School reports should always be obtained prior to the assessment. Parent or teacher-based questionnaires (e.g., Strengths and Difficulties Questionnaire (SDQ; Goodman, 1997), Developmental Behaviour Checklist (DBC; Einfeld & Tonge, 2002) can identify general difficulties, while longer informant-based instruments such as the Development and Well Being Assessment (DAWBA; Goodman *et al.*, 2000) can provide information about diagnosis. For specialist clinics (e.g., for children with autism), which frequently have long waiting lists, diagnosis-based questionnaires such as the Social Communication Questionnaire (SCQ; Rutter *et al.*, 2003) can help to avoid costly assessments of children who clearly do not meet diagnostic criteria. However, the value of such pre-assessment information relies heavily on the quality of the information provided, and should not constrain either the range of areas covered by the assessment or the potential formulations explored as part of the assessment.

Clinic-based assessments

Careful child observation in the clinic, with parents and with unfamiliar adults, provides important information. Thus, even before testing begins, much can be learned from observing the young person in the waiting room (see Chapter 33). Clinical observations can also inform which formal assessments to undertake, how best to conduct them and how results should

be interpreted. In addition, clinic-based assessments enable the clinician to control environmental variables in order to obtain the best standardized sample of behavior. They also make it possible systematically to vary environmental “presses” and the structure in which the child is observed to assess impact on behavior. Structured observational schedules exist for some specific disorders (e.g., Autism Diagnostic Observation Schedule (ADOS-2; Lord *et al.*, 2012); Disruptive Behavior Diagnostic Observation Schedule (DB-DOS; Wakschlag *et al.*, 2008)). However, some measures are expensive and require extensive training.

Interviewing children and young people and parents

Structured interviews are a crucial part of any clinical assessment, and many different instruments are available (see Chapter 33). These include those designed to assess a range of possible psychopathologies (e.g., Kiddie-SADS-Present and Lifetime Version (K-SADS-PL; Kaufman *et al.*, 1997) and measures that focus on specific disorders (e.g., the Autism Diagnostic Interview-Revised (ADI-R; Lord *et al.*, 1994)). It is also important to obtain the child’s own views of his or her difficulties and for school-aged children of average intellectual and language ability a range of well-standardized and -validated instruments, of varying lengths and complexity is available (see Chapter 33). However, informal conversation (e.g., about home life, school, friends, hobbies, likes, and dislikes, why they think they have come to the clinic, how they are feeling generally, etc.) can provide invaluable additional information. Tone of voice, facial expression, general attitude can also reveal a great deal about the young person’s mood and emotional state. Many young people

will be understandably reluctant to disclose information about personal issues or worries in front of their parents and will need to be interviewed alone, and this is clearly essential if child abuse or maltreatment is suspected. However, if appropriate, some time spent with both the young person and their parents together can provide important information about family relationships.

Interviewing very young or developmentally impaired children presents more difficulties, as standardized interviews tend to be inappropriate for their cognitive and/or linguistic level. Engaging them in play or viewing age-appropriate media may be informative (Beresford *et al.*, 2004). Because such children are distressed if separated from their parents it will usually be necessary to see them in the presence of a parent, which can provide additional valuable information.

Non-clinic-based assessment

A good-quality clinical assessment is time-consuming and requires expertise, but a few-hour assessment provides only a limited snap-shot of the child's functioning. Moreover, children's behavior in the clinic may not be representative of their behavior elsewhere. For example, a child who is polite, quiet and compliant may be highly disruptive in familiar settings. Parental reports may misrepresent the child's difficulties because of biases related to parents' background or problems. The father of a child with autism, for example, may underplay the difficulties, noting "I was just like that at his age and I don't have any problems now." School reports, too, can be biased. A well-behaved child with severe learning problems may be described as having no discernible difficulties, while a disruptive child of average IQ may be reported as failing academically as well as socially. Despite standardization in questionnaires, these, too, are not bias-free, and if respondents have intellectual or language problems they may not necessarily interpret questions correctly. In such circumstances, the only way to obtain more reliable information on the child and the factors that contribute to his or her difficulties is to supplement the clinical assessment with direct observations.

The need for non-clinic-based assessment is especially important when there is a discrepancy between the various accounts of behavior, for example, disagreements between parents and teachers concerning the nature or severity of the presenting difficulties, or when the behavior observed in the clinic does not tally with other reports. For example, a child referred for learning or behavioral difficulties at school may, on testing, show no obvious intellectual impairment. If more detailed assessment also fails to identify any specific cognitive/learning impairments then further investigation will be needed to explore possible home- or school-based factors (family disruption, parent-child relationship problems, bullying or emotional or mental health problems) that are affecting progress.

Difficulties in social relationships are a common reason for referrals to child and mental health services and informal observations can provide valuable information on the child's interaction with others across a range of different settings—for

example, with teachers and assistants within the classroom or with peers in the playground at school. Although difficulties in social interactions and social behavior (ranging from peer interactions to attachment relationships with parents/carers) are often the primary focus of such observations they can also provide information about many other aspects of the child or young person's functioning, including emotional responses (e.g., shyness, anxiety), activity levels, and motor skills.

Unstandardized assessments are particularly important for children who cannot complete other measures due to profound learning difficulties. Informal observations of the child interacting with a familiar adult can provide valuable information. The adults involved can also provide information about their interpretation of the child's responses or what is triggering a specific behavior. However, behaviors may be misinterpreted. For example, aggressive behavior may be a severely impaired child's main way of indicating distress, which adults can misinterpret as deliberate attempts to harm others. Alternatively, a classroom assistant may insist that the child "understands every word you say" although the child is, in fact, able to follow only a few simple commands in specific contexts (e.g., will respond to "Get your coat" because all the other children are going outside).

Psychological assessments conducted outside the clinic may also produce unpredicted findings. For example, in group settings (the home, classroom or a residential unit) reports of difficulties often focus on one particular individual. However, systematic observations sometimes indicate that the problem is not restricted to the referral case. For example, a teacher in a school for children with moderate learning difficulties had asked for help with a particular student who was described as being constantly off task and disrupting other pupils. Classroom assessments included counts of on task behaviors using very simple time sampling techniques (child not/sitting at desk at 15 min intervals). These indicated that the child concerned was off task no more than other pupils. However, when out of his desk he had a habit of dribbling and smearing saliva and it was this specific undesirable behavior that needed to be the focus of intervention.

In families, too, although one child is the focus of parental concerns, there may also be difficulties with regard to other siblings. A broad psychological assessment can be crucial in identifying these and in refocusing intervention on the wider family dynamics (see Chapter 39).

Formal psychometric assessment

Intelligence testing

Since the emergence of "intelligence testing" (Galton, 1883; Cattell, 1890), there has been much debate about what "intelligence" is and how to measure it. One approach defines intelligence as "what intelligence tests measure" (Sparrow & Davis, 2000). Spearman (1904) proposed his concept of a "g" or general factor, empirically derived from factor analysis. While the subsequent century-long debate about the existence and

nature of “g” has failed to reach consensus, most contemporary theories admit the presence of a general factor, with recent indications that this may have an identifiable brain basis (Duncan, 2010). There is strong evidence that intelligence tests measure something meaningful about development, cognitive abilities, and adaptive behavior. Thus, IQ scores show moderate (0.6) to high (0.8) stability (Watkins & Smith, 2013) and correlate highly with real-life outcomes, such as academic achievements and income (Fergusson *et al.*, 2005).

Standardized assessments

Understanding of psychometric theory and the statistical methods used to derive standardized scores is essential for evaluation of intelligence tests. Statistical methods, primarily factor analysis, have been used to derive global metrics of psychological constructs from individual test items. Many standardized tests have scaled scores with means of 100 and standard deviations of 15 although others use T-scores with means of 50 and standard deviations of 10. Standard scores are then used to define average, below average or superior ability depending on how many standard deviations above or below the general population mean a child’s performance lies (see Kaplan & Saccuzzo, 2013; for a comprehensive review). Figure 34.2 shows a model standardization/normal curve with the percentages of a population who would fall above/below the various standard deviation scores and the standard and T-scores derived in many IQ and developmental tests.

Findings from standardized tests then have to be related to the educational or clinical classification systems that operate in any country. These may differ from those used in the ICD-10 (WHO, 1993) and DSM-5 (American Psychiatric Association, 2013) classification systems—sometimes creating a tension between medical-led clinical teams and education-led school services. Thus, within the UK education system, an IQ between 70 and 50/55 is described as “moderate learning difficulty,”

whereas ICD-10/DSM-5 criteria define an IQ in this range as being indicative of “mild” intellectual impairment. Furthermore, terms such as “learning difficulty,” “learning disability” and “intellectual disability” tend to be used interchangeably, and confusingly. It is important in clinical practice for a technical summary of psychometric assessment results to be clear about the definition and use of terms employed to minimize misunderstanding.

What makes a “good” test?

In determining the applicability of any test, consideration should be given to the size, composition and diversity of the standardization sample in relation to the individual, group or setting for which it is to be used. Characteristics such as age, sex, educational, social, racial, economic, and geographical backgrounds of the normative sample are all important. For example, individuals with low IQ are often omitted from school-based standardization samples (Simonoff *et al.*, 2006)—leading to problems in the use of many IQ tests with children with more severe intellectual disabilities. When the test was normed is also crucial as there is likely to be an increase in scores in successive cohorts of children from any one country (the so-called “Flynn effect”), generally due to a combination of improvements in diet and education (Nijenhuis & van der Flier, 2013). Clinical reports should state the nature of the normative sample when this differs from the testing situation (e.g., test was normed in a different country).

Other critical test parameters are *reliability* and *validity*. The different types of reliability that are most relevant are split-half and test-retest reliability—the latter is particularly important for indicating the minimum test-retest time period that is vulnerable to practice and other learning effects. Some tests provide parallel forms to enable such difficulties to be minimized. Construct validity is usually documented by comparing test scores from the normative sample to scores on another established IQ test or to a previous version of the same test.

Figure 34.2 A model standardization/normal curve with percentages, Z-score and T-scores.

The final “test of a good test” is the *accessibility* and *relevance* of the test items to the population on whom the test is to be used. Particular considerations (e.g., on timed items) apply for children with sensory or physical limitations such as those with cerebral palsy or sight or hearing impairments. Some tests of general intelligence, such as the Wechsler tests, rely heavily on understanding verbal instructions; others specifically eliminate the need for verbal comprehension (see later). Another consideration is how attractive and engaging the materials are and more recent editions of many of the most widely used intelligence tests now use colorful and modern test stimuli.

Tests of general intelligence

Among the best-established tests are the Stanford-Binet—fifth edition (SB-5; Roid, 2003); the Differential Abilities Scale (DAS-II; Elliot, 2007) and its UK counterpart the British Abilities Scale (BAS-3; Elliot & Smith, 2011) and the suite of Wechsler tests (Wechsler Preschool and Primary Scale of Intelligence—fourth edition (WPPSI-IV; Wechsler, 2012); Wechsler Intelligence Scale for Children—fourth edition (WISC-IV; Wechsler, 2003); Wechsler Adult Intelligence Scale—fourth edition (WAIS-IV; Wechsler, 2008)). The age ranges and derived standardized scores of these widely used tests are summarized in Table 34.1. There is less emphasis than in previous versions on the Performance (PIQ) and Verbal (VIQ) Intelligence Scale scores, with a more neuropsychological approach to grouping different abilities, supported by results of factor analysis. These index scores are more closely tied to empirically based theories of intelligence and have greater potential remedial value in identifying individual profiles of cognitive strengths and weaknesses.

Other tests are modeled on different theories of intelligence and are also more explicitly linked to strategies for remediation. For example, the Kaufman Assessment Battery for Children-II (KABC-II; Kaufman & Kaufman, 2004) is derived from Luria’s (1966) neuropsychological model of information processing (simultaneous vs sequential) as opposed to information content (verbal vs visual-spatial). A valuable component of the Kaufman tests is the reduced reliance on verbal understanding/responding, so that non-verbal subtests can be both administered and responded to without speech. Many other tests of general intelligence are also available, as reviewed in Flanagan and Harrison (2012).

A general approach for supporting children’s progress and learning is to help them (and their parents and teachers) to use areas of relative strength to compensate for areas of relative weakness, for example, by using additional visual materials and structure for a child or young person with weaker verbal comprehension skills.

There are many brief IQ assessments available, such as the Wechsler Abbreviated Scale of Intelligence (WASI-II; Wechsler, 2011) and the Kaufman Brief Intelligence Test—second edition (K-BIT-2; Kaufman & Kaufman, 2006) and others that can be administered across whole school populations, such as the

Cognitive Abilities Test—third edition (CAT3; Lohman *et al.*, 2001). Such measures can usefully index general functioning for research purposes and can guide the clinician when a child with prior testing requires updated assessments to monitor progress. However, results can be misleading if wrongly applied in clinical settings. For example, achieving an average range IQ on a brief assessment does not rule out the presence of significant specific learning difficulties, which is more likely (but not always) to be picked up by a comprehensive omnibus test. Similarly, a low score alone does not provide detailed information about the nature of the child’s difficulties.

Assessments for infants and toddlers

Psychological assessment of infants and toddlers requires particular expertise with this age group (see Chapters 6 and 7).

Until the 1990s, the use of intelligence tests with preschool children and toddlers was controversial, both because of unease about the appropriateness of such testing and concerns regarding stability (Flanagan & Alfonso, 1995). However, in the past two decades, there has been considerable development of preschool tests. Several of the instruments reviewed earlier have extended the age range downwards to 2–3 years (e.g., SB-5; DAS-II/BAS-3; WPPSI IV). There has also been more cross-fertilization between the approach that psychologists have traditionally taken and that taken by developmental pediatricians in which there was a decades-old tradition of pediatric developmental assessments.

Stemming from the work of Ruth Griffiths (1935) and Mary Sheridan (1945), but also influenced by Piaget’s stages of infant and child development, several developmental assessments for infants and preschoolers have been developed. These include the Griffiths Mental Development Scales (Griffiths, 2006), Bayley Scales of Infant and Toddler Development (Bayley-III, 2005), and Mullen Scales of Early Learning (Mullen, 1995) (see Snow & Van Hemel, 2008 for comprehensive reviews of preschool assessments and Table 1). These tests involve direct assessments of young children’s abilities using play-based materials as well as observations of the child in the clinic and, in some cases, parental reports of the child’s functioning. They provide age-equivalent scores in domains of behavior such as fine and gross motor skills, expressive and receptive language ability, and early non-verbal conceptual reasoning and also allow an overall developmental quotient (akin to an IQ score for older children) to be calculated.

Caution needs to be employed in interpreting findings from assessments with infants under 2 years of age, particularly in terms of making judgements about likely outcome and prognosis. Even in cohorts of typically developing children, correlations between scores obtained in infancy and scores on tests completed later in childhood are only moderate, particularly when subdomains of functioning are considered (Aylward, 2004). In clinical samples including preterm infants (Hack *et al.*, 2005) and infants with autism (Charman *et al.*, 2005), the association between very early IQ/DQ scores and scores in mid-childhood

Table 34.1 Age ranges and derived standardization scores of widely used IQ and developmental assessments.

Test	Age range (years: months)	Key Standardized scores/subscales
<i>General Intelligence tests</i>		
British Abilities Scale—third edition (BAS-3; Elliot & Smith, 2011)	3:00 to 17:11	General conceptual ability Verbal ability Non-verbal reasoning ability Spatial ability Special non-verbal composite
Differential Abilities Scale—second edition (DAS-II; Elliot, 2007)	2:6 to 17:11	General conceptual ability score Verbal ability Non-verbal reasoning ability Spatial ability Special non-verbal composite
Stanford-Binet—fifth edition (SB-5; Roid, 2003)	2:00 to 85+	Full scale IQ Verbal IQ Non-verbal IQ Brief IQ 5 Factors scores: fluid, knowledge, quantitative, visual-spatial, and working memory
Wechsler Preschool and Primary Scale of Intelligence—fourth edition (WPPSI-IV; Wechsler, 2012)	2:6 to 7:7	Full scale IQ Verbal comprehension index Visual spatial index Working memory index Fluid reasoning index Processing speed index
Wechsler Intelligence Scale for Children—fourth edition (WISC-IV; Wechsler, 2003)	6:00 to 16:11	Full scale IQ Verbal comprehension index Perceptual reasoning Working memory index Processing speed index
Wechsler Adult Intelligence Scale—fourth edition (WAIS-IV; Wechsler, 2008)	16:00 to 90:11	Full Scale IQ Verbal comprehension index Perceptual reasoning Working memory index Processing speed index
Kaufman Assessment Battery for Children-II (KABC-II; Kaufman & Kaufman, 2004)	3:00 to 18:11	Mental processing composite Fluid-crystallized index Non-verbal composite Simultaneous processing Sequential processing
<i>Test</i>	<i>Age range (months)</i>	<i>Key Standardized scores/subscales</i>
<i>Developmental tests</i>		
Bayley Scales of Infant and Toddler Development—third edition (Bayley-III, 2005)	1–42	Adaptive behavior Cognitive Language Motor Social–emotional
Griffiths Mental Development Scales (Griffiths, 2006)	1–96	General quotient Locomotor Personal–social Language Eye and hand co-ordination Performance
Mullen Scales of Early Learning (Mullen, 1995)	1–68	Early learning composite Gross motor Fine motor Visual reception Expressive language Receptive language

is modest to poor. This partly reflects difficulties inherent in infant testing due to the different nature of infant vs. childhood developmental accomplishments and hence the skills tested at different ages, as well as the fact that environmental influences become more evident after 2 years of age. After the age of 2 years, the stability of test scores significantly increases (Aylward, 2009).

Tests of other abilities

Although the types of tests described earlier will provide an indication of the child's overall level in verbal and visuo-spatial skills, developmental difficulties in other domains also have a significant impact on functioning. Thus, a comprehensive assessment of a child's skills should also include an evaluation of his/her functional language and communication (see Chapter 52), psychomotor and sensory difficulties (see Chapter 47), executive functioning (including working memory and attention) and semantic and episodic memory.

Assessment of executive functioning, attention, and memory

Assessments of attention and executive functioning include the Delis-Kaplan Executive Functions System (Delis *et al.*, 2001), the Test of Everyday Attention for Children (TEA-Ch; Manly *et al.*, 1998), the Conners' Continuous Performance Test (Conners, 2004), the Developmental NEuroPSYchological Assessment (NEPSY; Korkman *et al.*, 2007), and the Behavioral Assessment of the Dysexecutive Syndrome in Children (BADSC; Emslie *et al.*, 2003). It has also been observed that clinic-based assessments of executive functioning often do not reflect how children behave in other settings, for example, in class (Barney *et al.*, 2011). Clinic-based assessments using structured tests should perhaps be considered to indicate children's *optimum* or potential level of skill, whereas observations of their skills in their everyday environment (as elicited by observation and the use of structured questionnaires such as the Behavior Rating Inventory of Executive Functioning (BRIEF; Gioia *et al.*, 2000)) show the impact of their difficulties on their lives.

Assessments of memory include measures of verbal and visual memory for immediate and delayed recall. It is useful to assess both retrieval and recognition abilities, as the child's performance under different conditions will inform intervention methods. Batteries of tests such as the Children's Memory Scale (Cohen, 1997), the Rivermead Behavioral Memory Test for Children (Wilson *et al.*, 1991), the Test of Memory and Learning (Reynolds & Bigler, 2007), and the Wide Range Assessment of Memory and Learning (Sheslow & Adams, 1990) cover these various facets of memory. Additionally, working memory can be assessed in more detail (e.g., the Working Memory Test Battery for Children, Gathercole & Pickering, 2001). Children's everyday (episodic) memory should be considered and their rate of forgetting should be determined. Parents and teachers often observe that children appear to learn something one day and have forgotten it the next. Memory tests generally

only test 20–30 min later in the delayed condition and the rate of forgetting over longer periods of time may need to be considered.

Some psychologists, usually those with training in neuropsychology, are able to assess skills within all these domains. The benefit of a single assessment, covering a broad range of areas, is that the assessor can provide an overview of how areas of specific strength and weakness inter-relate and contribute toward the child's behavioral presentation. More typically, however, a multi-professional assessment is required to ensure that skills in all areas are adequately assessed.

Achievement tests

Assessments of school-based attainments, including reading, spelling, and maths are important because these skills are so critical to children's progress through school. It is useful to use batteries that are co-normed with measures of intellectual ability so that clinical discrepancies between skills can be measured. Batteries such as the Wide Range Achievement Test (Wilkinson & Robertson, 2006) and the Wechsler Individual Achievement Test (Wechsler, 2009) are designed to be used alongside the Wechsler IQ tests. Assessments that measure literacy usually focus on word reading, reading fluency, reading comprehension, and spelling. An area that can be hard to assess formally is children's ability to express their ideas on paper, an observed difficulty often commented on by teachers and parents.

When schools assess children's early academic progress, measures to determine their reading level and mathematical skills are usually administered, that is, skills that have been explicitly taught and possibly over-learned. Such assessments do not take into account the development of children's learning and thinking skills more broadly and do not consider how other cognitive difficulties can have a longer-term impact on the ability to succeed beyond school. Rather than focussing only on specific difficulties a broader-based assessment that incorporates academic attainments as well as screening for difficulties in the dynamic application of learned skills (e.g., tasks requiring a degree of working memory and problem-solving) would perhaps highlight where individuals needed a more wide-reaching learning intervention (see Chapter 53).

Special considerations

When undertaking any psychological assessment, it is important to consider diverse issues, highlighted earlier, particularly when testing children with special needs. Specialists have informed much of our knowledge about these issues.

Low IQ

The most likely reasons for very young children to be referred to clinical services are delays in motor, cognitive or language development. Pediatric assessments based on semi-structured observations of the child, reviewed earlier, can identify children

with severe and global delays, but they may fail to detect more subtle developmental problems. If direct testing is not possible, or the results are considered unreliable because the child is too distressed or anxious, it will be necessary to rely on parental information.

Several informant-based measures are available that provide information on the child's progress across a range of different domains. Some, such as the Assessment of Basic Language and Learning Skills—Revised (ABLLS-R; Partington, 2006) are designed to identify specific areas of deficit in order to guide skill remediation programmes. Others (e.g., the Vineland Adaptive Behavior Scales (VABS-II; Sparrow *et al.*, 2005) or the Adaptive Behavior Assessment System (ABAS; Harrison & Oakland, 2003)) allow assessment of the child's level in comparison to other children of the same age. Because these measures are based on parental report they lack the objectivity of standardized, child-based assessments. Thus, some parents may overestimate the child's level of ability in certain areas, or, if the environment is very restrictive, the child may not have had the opportunity to demonstrate skills in some domains. However, these issues can often be resolved by careful questioning. It is also important to be aware that adaptive behavior scores are not equivalent to IQ scores and in some conditions, such as autism, a child's Vineland score, for example, may be much lower than his or her score on a standard IQ test (Charman *et al.*, 2011). Nevertheless, these types of assessment can be particularly helpful in providing a picture of a young person's developmental profile and everyday functioning. For very young or severely developmentally delayed children the information they provide can be more useful for planning educational and intervention programmes than a standard IQ score.

Testing hearing and/or language impaired children

Among tests that have been specifically developed for children with hearing or language difficulties are the Leiter International Performance Scale—Revised (Leiter-R; Roid & Miller, 1997) and the Snijders-Oomen Nonverbal Intelligence Scale—Revised (SON-R; Snijders *et al.*, 1989). These can be administered without spoken instructions, using demonstrations of correct responses. Ideally, a comprehensive clinical assessment should include measures of language understanding and expression (in the child's own language, if possible; if not, in the language in which he/she is being educated), as communicative function (note this is not the same as spoken language nor the same as Verbal IQ) is key to adaptive learning, behavior and development (see Chapter 52).

Rare disorders

Psychologists occasionally will be asked to assess children with specific and/or rare genetic syndromes, many involving particular cognitive profiles (Simons, 2007). For example, children with Williams syndrome tend to have mild—to moderate global intellectual disabilities and specific learning difficulties (e.g., in mathematics) but expressive language and social skills

are relatively well preserved; children with Fragile X show weaknesses in quantitative skills and in short-term memory for abstract stimuli, whereas short-term memory for visually presented, meaningful stimuli is a relative strength. Although, within all genetic disorders, there is considerable individual variation, it is important that the psychologist is aware of the cognitive profiles typically related to the condition; the assessment should also focus on highlighting the child's particular pattern of strengths and weaknesses.

Different cultures and communities

There are significant limitations and challenges in adapting and/or using tests outside the culture and community in which they have been developed and normed. Carter *et al.* (2005) identified five broad categories relevant to cross-cultural assessment: the influence of culture on performance, familiarity with the testing situation, the effect of formal education, language issues, and picture recognition. Even when translation of tests has been undertaken, there is a need to be cautious in interpreting and reporting standardized scores. Sánchez-Escobedo *et al.* (2011) compared performance across English-speaking children in American schools, Spanish-speaking children in American schools and Spanish-speaking children in Mexican schools on parallel versions of the WISC-IV. Subtest standard scores derived from the same raw score differed by as much as 1 standard deviation. Differences in the nature of the standardization samples, including hard-to-measure factors such as differential exposure to formal testing in schools and familiarity even with adapted test materials, most likely underlie the differences found. Encouraged by the test publishing houses, there are an increasing number of translations of some of the most widely available psychometric tests that are to be welcomed. However, the difficulties inherent in adapting a test developed in one culture and community to another need to be borne in mind. In communities where no culturally appropriate formal tests are available, greater reliance on information from parents and from schools will be required although, when possible, this should be augmented by direct observation both during structured and unstructured activities.

Interpreting and reporting test scores in “atypical” children

Standardized, clinic-based assessments are designed to provide information about a child's progress compared to that of a typically developing, same age, peer group. However, particularly in the case of children with developmental or other disabilities, it is possible for children to achieve a score that is within the normal range for their age while completing the test in an unusual way. For example, a child with autism tested on the WISC might obtain scores at ceiling on the subtests of Vocabulary and Information because of his or her extensive knowledge of facts and ability to define words. Although scores on other verbal subtests (e.g., Similarities or Comprehension) may be very low, the overall verbal ability score can, nevertheless, be well

within the average range. Moreover, informal interactions with that same child may indicate that his social-communication skills are highly impaired. Another child might obtain very low scores on non-verbal tests not because of poor psychomotor or processing skills, but because he or she is highly anxious or suffering from Obsessive Compulsive Disorder (OCD). Thus, although the score on any psychometric assessment is important, careful observations of the child's performance provide some of the most clinically useful information. Test scores alone should never be considered in the absence of a description of test behavior.

Unstandardized assessments

With children with intellectual or learning disabilities who are functioning at a level well below their age, clinicians will often use assessments standardized for younger children because they are more appealing and accessible. Using tests in such a way can elicit useful information about a child's ability to respond to novel stimuli and co-operate with the formal assessment process. However, in such circumstances, it is important to be aware of the problems inherent in using and interpreting out-of-age tests results or relying on age equivalents to provide an indication of a child's ability. When using out-of-norm tests, the clinician uses the raw score to determine at what age such a raw score would be typical. In such cases, it is important to be aware of the statistical basis upon which such scores are calculated and the extent to which the skill being assessed develops in a linear or step-wise fashion. The clinician should also be explicit about exactly what is being measured and how the presentation of that skill would compare with a typically developing child with the same age equivalent (Bracken, 1988). For example, if a typically developing 3 year old child obtains an age equivalent score of 3 years (standard score = 100) on a measure of expressive language that involves naming single pictures, it is reasonable to assume that other aspects of his or her language competence are at a similar level. If a 12-year-old child with autism is able to name enough pictures to achieve the same raw score this may have been acquired via a very different process, for example, by learning to repeat large numbers of common words. Other aspects of his or her language development may be at a very different level. Thus, although the children's raw scores on the test are identical, there may be little else that is similar about their language abilities or communication skills.

Considerations in the testing environment

Psychologists need to be aware of factors that influence test performance, such as having observers during the assessment (e.g., parents or trainees), testing the child in a familiar versus unfamiliar environment and testing the child at the end of the school day. Occasionally, too, particularly when testing children with significant comprehension problems, it may be necessary to modify test instructions somewhat, perhaps giving additional verbal or non-verbal cues on early test items, or starting at a lower level than the testing manual indicates, to ensure that the

child understands what is expected. Although these modifications can help to increase co-operation and test compliance, it is always important to record any deviations from standard administration procedures.

At all times, psychologists need to ensure the validity of their assessment and, where appropriate, assess the child's effort during testing (Blaskewitz *et al.*, 2008; Kirkwood *et al.*, 2012). Children need to be encouraged to do their best before the session commences. If there are suspicions that the child is not co-operating, for whatever reason, there are tests that can be used to determine whether or not she/he is performing optimally (e.g., Test of Memory and Malinger; Tombaugh, 1996; Reliable Digit Span test; Kirkwood *et al.*, 2011).

It is also important to ensure that poor performance is only interpreted as lack of effort when this is clearly the case. Children with specific learning difficulties may fail some assessments because of the extra effort involved, and it is normal for children's attention to vary during the assessment process. Children may also be tired after a long journey, anxious about the unfamiliar assessment situation or not feeling well. The clinician needs to take these variables into account before concluding a poor performance is down to lack of effort.

Finally, there may be times when testing is not appropriate at all, for example, where there have been previous recent administrations of the same or similar batteries. This might be the case, for example, if parents are determined to enroll their child in a programme for gifted children and have previously sent him or her for several other assessments. While the time needed between repeat assessments is not usually explicitly stated in test instructions, the utility and reliability of repeat testing needs to be considered by the practitioner to avoid scores being inflated by practice effects (or possibly deflated because the child sees no reason to repeat the same activities over again) (Calamia *et al.*, 2012).

What to report and how

Once the assessment is complete, the next step is to pass on this information to those involved in the most accessible and informative way. Some teams provide immediate feedback even if this is sometimes preliminary. Others ask the family to return when all the information has been fully collated. Whichever option is taken, it is essential that the child and family are aware what will happen at the end of the assessment, when oral feedback will be given, and when they will receive written reports. Decisions also need to be taken as to whether feedback will be given to the child and family together or individually. This will depend on the age and developmental level of the child as well as the quality of family relationships. The child and family must also be given time to raise their own questions and concerns, either on the day of the assessment or at a pre-arranged time thereafter.

Written reports must be provided within a set period and be appropriate for the recipients. Many families (and indeed many

professionals) are unable to interpret technical details such as t-scores, confidence intervals, percentiles or algorithm scores. Even IQ scores can give rise to confusion, with some families being very upset that their child has an “IQ of 99” when they had been told previously he was of “average ability”! Instead, it is usually better to report IQ results in terms of ranges, rather than a single score.

In general, the findings from the assessment should be reported in as concise and straightforward a way, as appropriate for each family. Detailed scores of IQ or other assessments can be included as a separate appendix that can be supplied to the family or other services as needed. When summarizing the outcome of the assessment to the child, the style of the report letter should be carefully adapted to suit his or her developmental, linguistic, and emotional needs. Following a psychological assessment, especially when undertaken as part of a multi-disciplinary team assessment, the results should be discussed not only with other team members but also with education professionals working with the child or young person so that a jointly agreed approach can be developed to support the child’s learning and/or behavior management. It is important that a consistent approach to support and intervention is adopted at home and school.

Reports to schools should provide all relevant educational information but it is important that any confidential personal information provided by the family is not inadvertently included. In reporting to court or social services, impressions of the relationship between the child and parents, or information on the young person’s behavior and social history may be more important than a focus on details of IQ scores

Professional issues for psychologists

Psychologists are normally regulated by a professional body (e.g., the Health and Care Professions Council in the United Kingdom; the American Psychological Association in the United States of America) and have a responsibility to maintain their Continuing Professional Development (CPD). This usually means ensuring that they have spent a certain amount of time each year up-dating their knowledge through attendance at conferences and reading current research material and having regular professional supervision. Accessing supervision and current literature can be more challenging for psychologists working independently but is no less critical.

Psychologists are bound by a code of practice that is designed to ensure the safety of their clients, both through regulating their behavior toward the people with whom they work and to ensure a certain standard of practice. Having a regulated profession means that psychologists should work in a reasonably uniform way. They have a responsibility to maintain test security, to share test results with other psychologists where appropriate to avoid skewing later test results (e.g., through a practice effect or test fatigue), to report any unusual administration methods, such as testing the limits, which may affect later administration of the same test.

Using psychological assessments to inform intervention

Assessing behavioral functions

One of the most common reasons why children are referred to specialist clinical services is the presence of behaviors that are disturbing or distressing for themselves, their families, peers, teachers or society more generally. Such behaviors may result from many different, and often multiple, causes. They may be a reaction to environmental factors (e.g., neglect, abuse, bullying, excessive demands from school or family) or, for example, in the case of children with developmental disorders, they may be the individual’s most effective means of escaping from undesired situations or of gaining attention. Emotional or psychiatric disorders may also present initially as behavioral disturbance. Successful intervention necessitates a clear understanding of the factors that may be causing or maintaining problem behaviors or interfering with learning but very often it is not possible to determine these from the initial referral. In such cases, the psychological assessment will also require a detailed analysis of the problem(s) (see Chapter 38). Anxiety, for example, is frequently associated with high levels of arousal (see Chapter 60); irritability is a common symptom of depression (see Chapter 63); attention deficit hyperactivity disorder (ADHD) is typically related to poor impulse control (see Chapter 55) and these secondary symptoms can often lead to apparently unprovoked explosions of anger, disruption, or aggression.

One critical aspect of psychological assessments used within the context of an intervention is the extent to which they are sensitive to change. Some aspects of the development of standardized psychometric tests have been influenced by the notion of a stable constitutional factor such as IQ. Non-standardized assessments can be of value to evaluate interventions, though they need to be systematic and reliable. The combination of formal and informal psychological assessments may also indicate that a child has more fundamental learning or behavior problems than were initially recognized, as well as revealing inadequacies or inconsistencies in the ways these are dealt with at home or at school. In such cases, these assessments can be essential in establishing the basis for more systematic cognitive, behavioral, or pharmacological interventions and for monitoring the effects of the intervention over time (see Chapter 14).

Although there are many different and widely used interventions for children with learning and behavioral difficulties few have a sound evidence base, particularly when applied in non-experimental settings. For example, the Response to Intervention model has become a standard model of intervention for children with learning difficulties across the United States. Response to Intervention was intended to provide a means of delivering early intervention to all children presenting with learning difficulties in school, with interventions of greater intensity and specificity being delivered to those who failed to respond to the earlier, broader intervention input. The tiered

approach to intervention has some similarity to Dynamic Assessment, which is intended to provide a specific analysis of individual children's approaches to problems to enable the generation of a process-oriented model of intervention, for example, through providing graduated prompts to enable a child to achieve successful task completion (Tzuriel, 2000). However, providing this intervention in a group format, as is needed in the Response to Intervention model, rather diminishes the potential strengths of the model because children with severe difficulties are not identified at the early stages and potential intervention time is lost (Reynolds & Shaywitz, 2009). Information gleaned from observing individual children's response to interventions, if rigidly measured, could provide valuable information about intervention efficacy (initially on a single-case basis). A wide range of literacy and educational interventions are available; some but not all of which have a sound evidence base (see Chapters 41, 52, and 53).

There are a few intervention strategies available to tackle difficulties arising from specific neuropsychological impairments. These include computer-based working memory systems, such as Cogmed Working Memory Training for children with clearly assessed specific working memory weaknesses, although it is not clear the extent to which gains made during training have a functional impact (Shipstead *et al.*, 2012). Memory support strategies, such as errorless learning, for children with episodic memory and executive functioning weaknesses, are increasingly being developed because of evidence from neuropsychological investigations of children's learning abilities. By using psychological assessments to provide detailed information about the individual's strengths and weaknesses, targeted interventions of this kind can be evaluated through single-case designs. These allow the broader impact of an intervention, such as working memory training on academic attainments and behavior, to be accurately monitored.

The value of single case research

All interventions are likely to be based, at least initially, on information from single-case data and, although evidence from randomized control trials is considered the gold-standard on which to base therapy, many aspects of behavioral interventions have a strong evidence base from multiple case series data (Kratonchwill *et al.*, 2013). Single case design methodology, employing strategies such as multiple baseline and reversal techniques is also important in demonstrating the potential effectiveness of novel or individualized treatments. Note that it is important not to overlook information on interventions that have been effective for individual children or young people and robust methods for evaluating the efficacy of single-case interventions can be applied (Perdices & Tate, 2009).

For all children, even when well-established intervention methods are used, these need to be assessed in terms of the benefit for that individual. For example, in schools, children who are making slow progress in the acquisition of early literacy skills may automatically be assigned to a phonics intervention

group without any formal assessment to determine whether phonological difficulties are indeed the root of their literacy difficulties. Assessment of the child's skills and difficulties prior to and during the intervention is essential in order to determine if the child is learning the skill being taught and whether it is generalizing to improve access to the curriculum more broadly.

Single case-study design is particularly useful for assessing the best learning environment for a child. For example, when children have specific difficulties, such as specific language impairment, a split placement may be used, with the child dividing their time between a language unit and the mainstream class. Individual assessment over a period of time can determine their level of learning and social engagement in both settings to aid in future placement decisions. The data collected should include time on task, work completed independently and learning targets achieved as well as progress with language targets.

Detailed monitoring of individual children's progress is needed to ensure that strategies, assumed to be beneficial, are not inadvertently harming children's learning. Although children with special needs are often provided with additional support in mainstream classes using teaching assistants, this input can potentially limit the child's contact time with the teacher and has been shown to slow, rather than accelerate progress (Blatchford *et al.*, 2009). All too often classroom assistants for children with special needs have little or no training or support to ensure that they are actively facilitating learning. However, with adequate training and supervision non-professional staff are able to implement evidence-based intervention programmes effectively (see Chapter 41).

Conclusions

Psychological assessment of children and young people may be undertaken for a variety of reasons. Usually, the assessment will be a response to concerns that a parent, other health-care professional or teacher has about the child or young person's development or behavior. The domains that need to be considered in any assessment are wide and most assessments should consider both development and behavior, alongside the child's emotional well-being (Murray & Farrington, 2010). The family, home and school environment—its impact on the child and the child's impact on those with whom they come into contact—should also usually be considered as part of any psychological assessment.

Cognitive assessment can be a vital part of the assessment process, and requires a rigorous and methodological approach to testing together with an understanding of psychological and statistical theory. However, psychometric assessment is neither the psychologist's only nor indeed primary role. Thus, we have emphasized the crucial importance that far broader, wide-ranging and theory-driven assessment plays in formulating and systematically testing hypotheses about a child's difficulties. The results of a hypothesis-led assessment will

provide a psychological framework for conceptualizing the child or young person's difficulties that, in turn, should guide and underpin approaches to intervention and remediation within the same hypothesis-testing framework.

CHAPTER 35

Physical examination and medical investigation

Kenneth E. Towbin

Emotion and Development Branch, National Institute of Mental Health, Intramural Research Program, Bethesda, MD, USA
Department of Psychiatry and Behavioral Health, The George Washington University School of Medicine, Washington, DC, USA

Introduction

Child psychiatry is a medical subspecialty that is closely related to child neurology and general pediatrics. While the primary focus of child psychiatry is mental disorders, practitioners must be ever mindful of the inextricable links among “mental,” “neurological,” and other “medical” symptoms. Furthermore, a basic principle of the field is that mental disorders are brain disorders that affect perception, thinking, learning, behavior, social interaction, and mood. Therefore, when making a diagnosis and during treatment, the child psychiatrist and all child mental health professionals must be alert to medical and neurological disorders that produce psychiatric symptoms, influence treatment interventions, and affect the outcome. Modern child psychiatry sees conditions as rooted in both biology and the mind, and it acknowledges the continuous interplay between these domains. Child mental health professionals recognize that a child’s body is affected by the child’s environment and by the way that child thinks and acts. Clearly, psychiatric disorders (e.g., eating disorders, depression, psychosis, psychosomatic fatigue, conversion symptoms), as well as the somatic treatments that are often prescribed, can affect pediatric growth and general medical health. However, child mental health professionals also know that various medical problems influence the child’s development and mental well-being. For these reasons, the physical examination and evaluation of the patient—drawing information from what is reported and an examination of the patient’s body—are fundamental to a comprehensive understanding of that individual.

There are other influences to be considered along with biomedical processes. It is equally fundamental to our field to appreciate the power of experiences, relationships, and the context of a child’s life. These have a formidable effect on how that child develops and thinks; one must account for them in formulating the child’s problems and treatment. The

sophisticated, modern view is that the course of development and disorders (e.g., onset, severity) are a function of biological and nonbiological forces acting through a complex interaction of risk and protective factors (Rutter *et al.*, 2006; Kendler & Baker, 2007; Meaney, 2010; Rutter, 2012).

The purpose of this chapter is to provide guidelines for clinicians to follow as part of a standard medical assessment of the child. The need to perform such an assessment follows from the fundamental principle that it is essential to discover biologically manifest features or observable risks (constitutional or acquired) that contribute to symptoms associated with a mental disorder. However, the astute clinician knows that physical and medical investigations are not sufficient to have a full grasp of the determinants of a patient’s condition.

The physical examination in child psychiatry is a part of the doctor’s relationship with the patient, the patient’s family, and in many cases, other healthcare providers in the patient’s life. Physicians are mindful of this as they approach their patients and their patients’ families. The manner with which the examination is conducted will communicate a great deal, much of it non-verbally, to the patient; the psychiatrist’s way of conducting the examination plainly conveys how the patient’s identity, thoughts, emotions, and physical feelings are regarded. Similarly, most parents are keenly aware that physical contact with their child has profound significance; it arouses concern and invites protective instincts.

The medical examination reflects a scientific approach. Physicians begin with gathering data, such as the primary complaint and the history of its onset and course. As the data are being gathered, they consider hypotheses about the differential diagnosis, potential contributions to the expression of those symptoms, and prognosis. Medical and laboratory assessments are not “fishing expeditions”; they test specific hypotheses that arise from listening carefully to the chief complaint(s) and history. Laboratory and medical evaluations are tools that facilitate the

process of narrowing the differential diagnosis and hypotheses into a workable treatment plan and approach to the child's care. The process is a "two-way street" in which laboratory and medical data can raise new hypotheses, support existing ones, and refute others (see Chapter 32).

All child mental health professionals consider the context of their patients' healthcare because this will guide what role and which parts of the examination they must perform in detail. Thus, the medical evaluation entails more than the basic history and course of illness. Child mental health professionals consider the scope of their involvement and their place in their patients' overall medical care. Child mental health professionals should be mindful of what is feasible, what part of their patients' care falls to them alone, who has the most expertise to pursue the workup, and what should be performed by (or in collaboration) with others. It is common sense that a child without basic healthcare or access to care will face insurmountable barriers to fulfilling recommendations for various forms of ancillary medical tests, such as MRI scans or extensive metabolic assessments. Conversely, when a child has ready access to routine pediatric care, the approach should take this into account when planning the workup and ordering tests. Child mental health professionals consider their patients' general health, history of prior assessments, and current healthcare relationships. When a child's care includes other healthcare providers, child mental health professionals think about the basic data others will need in order to pursue more focused, additional studies. Child mental health professionals consider these collaborations carefully and frame specific questions or hypotheses for their collaborators. For example, if a psychiatrist believes a child might have anemia, it is logical to confirm this by obtaining a complete blood count, serum hemoglobin, and hematocrit prior to referring the child for a more comprehensive workup.

The medical history

The medical history is a cornerstone of the medical evaluation and should not be omitted. It encompasses the child's current general health, health history, developmental health history, and family medical history.

The current health history is generally understood to include all current illnesses, recurrent conditions, allergies, and current and past medications. In the context of psychiatric care, it also should include the child's living conditions, socioeconomic circumstances, and access to healthcare. In more developed countries clinicians may make the tacit assumption that children have primary care providers, satisfactory nutrition, and everything they need for basic hygiene. However, one should not assume this to be the case for all children. For example, some children reside in homes or communities where they face deprivation and/or neglect, in low- and middle-income countries (LAMIC), or in poverty (in developed or LAMIC countries)

where principal foundations of health are lacking. Thus, inquiring about these components is necessary. As a part of a routine medical history, it is important to ask about the child's diet, activity/exercise level, and whether either parent or child has concerns about how the child is growing or feeling physically. These questions are particularly salient when evaluating children for the possibility of an eating disorder or depression.

The developmental history can also inform the clinician about a broad range of risks in the child's life. This can also influence the clinician's evaluation of any concurrent mental health problem. When exploring the prenatal history one can listen for significant risks prior to the child's birth, such as family medical/psychiatric history, sources of stress for the family, how the family coped with those stressors, and the barriers to healthcare. The course of the pregnancy can convey information about constitutional and environmental influences and perinatal events. These deserve further exploration because they may continue to affect the child. As in general pediatrics the developmental history includes the review of developmental milestones and includes the feeding history, development of gross and fine motor skills, coordination, language, social abilities (including peer relationships), school/academic functioning, and overall adaptive functioning in communication, daily living skills, socialization, and motor domains (Gerber *et al.*, 2010; Wilks *et al.*, 2010; Gerber *et al.*, 2011). There are established norms for many of these milestones and screening instruments (Sparrow *et al.*, 1984; Frankenburg *et al.*, 1992; Sparrow *et al.*, 2005; Drotar *et al.*, 2008; CDC (Centers for Disease Control and Prevention), 2011) that are helpful when acquiring information about delays or deficits in the past or present. A history of developmental delays and deviances should alert the clinician to the possibility of a neurodevelopmental disorder (see Chapter 32). For older children, it is important to gather a history of work activities. Also, it is now standard practice to inquire about past or recent exposure to traumatic events (interpersonal or natural), abuse, being victimized or bullied, and any exposure to violence at home, in the community, or at school.

The past medical history typically includes the patient's past and current medical illnesses, surgical history, any hospitalizations, and a review of any complications from common childhood illnesses or from medications. As suggested, learning the history may raise questions that go beyond mere medical data. The past medical history relays important information about the context of the child's past and present. Medical illness can impair the child's psychological health and the family's relationship with the child. Juvenile onset conditions (e.g., diabetes, cancer, epilepsy, or rheumatoid arthritis) or congenital disorders (e.g., heart, blood, or immune diseases) will have profound effects on psychological, social, and physical development. Even seemingly ordinary childhood events can cue the child mental health professional to potentially relevant psychiatric concerns. For example, a history of repeated accidents, fractures, or injuries (particularly concussions) could lead to questions about safety, supervision of the patient, impulsivity, thrill-seeking,

mood disorder, or risk-taking. Some psychiatric conditions, such as attention deficit hyperactivity disorder (ADHD) or a depressive disorder could also contribute to such events. Similarly, relatively common chronic or recurrent childhood maladies can shape the child's perspective on the world. Asking about asthma, bowel and bladder function, headaches, ear infections, and tics (and other repetitive movements) is important because these conditions may associate with psychiatric symptoms, influence psychological development, have profound effects on a child's day-to-day life, and/or involve treatments that affect mood and behavior. Also, a child psychiatrist will need to know whether psychotropic medications will interact with drugs that are already being taken for other conditions. In addition, asking about unusual reactions to any drugs may inform the psychiatrist about adverse effects that could arise with future psychotropic medications.

The family medical history is a major part of the patient's medical history. The family's medical history informs the child mental health professional about the patient's risk for developing medical and psychiatric disorders and suggests possible medical disorders that produce psychiatric symptoms. Furthermore, should a parent, guardian, or sibling have a serious medical or psychiatric disorder it is likely to have an impact on the family's life and the child. Learning the family medical history can inform the mental health professional about past and current events and circumstances in the patient's life that are troubling and have an influence on the patient's psychological development. While a single chapter could never catalog all the ways a medical disorder can influence a child or family, some conditions are mentioned here because they are relatively more heritable, particularly likely to produce psychiatric symptoms, or convey an elevated risk of adverse reactions to somatic treatments.

A family history of cardiac illness is an exemplar. While family history for cardiac disease in elderly relatives is common, such a history assumes compelling relevance for the child's medical and psychiatric care when there is a family history of childhood onset cardiac disorders (e.g., malformations, arrhythmias), or sudden death in young family members. A family history for myocardial infarction or sudden death in young family members indicates an elevated risk of cardiac conduction or myocardial diseases in the patient (Tan & Judge, 2012). Moreover, some psychiatric medications can increase the risk of a cardiac event in a vulnerable patient (Beach *et al.*, 2013). There has been a particular increase in concerns about cardiovascular effects of psychostimulant medications, and these concerns should require more extensive evaluations in children with a family history of heart conditions, particular sudden death or arrhythmias. In this instance, learning this history would prompt a more thorough characterization of the patient's current cardiac function (e.g., a baseline electrocardiogram (ECG), exercise stress testing) and close monitoring for ECG changes during initiation and subsequent to dose increments with some medications. Consultations with the child's usual pediatric care provider also would likely be indicated. Some aspects of the relationship between cardiac history and symptomatic presentation of

mental health problems remain contentious. For example, focus on a relationship between mitral valve prolapse (in the child or family) and anxiety was popular in the 1980s and 1990s. However, more recent evidence suggests that the relationship is weak if it exists at all (Weisse, 2007; Filho *et al.*, 2011).

A family history of endocrine disorders is another example. A family history of diabetes or hypothyroidism can increase the likelihood that the patient will have a similar disorder contributing to the psychiatric symptoms. A family history of diabetes type 2 (DM2) is a risk factor for developing DM2 (Wareham *et al.*, 2002; Rodríguez-Moran *et al.*, 2010). An overweight child who presents with depression and a strong family history for DM2 warrants consideration of hyperglycemia contributing to depression (Hannon *et al.*, 2013). A family history of diabetes also increases the risk for additional weight gain and developing diabetes while on psychotropic medication (Amed *et al.*, 2011). Similarly, there are major genetic contributions to development of both hyperthyroidism and Hashimoto's thyroiditis, which produces hypothyroidism (Ban & Tomer, 2005; Cooper *et al.*, 2012). When a patient is being evaluated for depression and gives a family history of thyroid disease, this suggests a greater risk for a contribution from thyroid dysfunction compared with someone without such a family history.

A family history of neurological disorders should be reviewed. Although the most common severe inherited neurological disorders have a very early onset, often in infancy (e.g., gangliosidoses), or typically begin in adulthood (e.g., Huntington chorea, dementia), a few begin in childhood and adolescence (e.g., Wilson's disease). Family and personal history is often the first clue to the presence of such problems. In addition, less severe, more common inherited neurological conditions that produce psychiatric symptoms, such as chronic tic disorders, have their peak incidence during childhood. The family history may be important for treatment as well. For example, a family history of glaucoma increases the risk of developing it with some pharmacological treatments such as selective serotonin reuptake inhibitors (SSRIs) and atypical antipsychotic drugs (Richa & Yazbek, 2010).

Summary key points of the medical history

- It is essential to maintain a continuous awareness of medical disorders that can produce or result from psychiatric disorders.
- Recognizing the context of psychiatric care within the patient's overall healthcare guides the role and what parts of the examination the psychiatrist will perform.
- The medical history is a cornerstone of the medical evaluation.
- The medical examination reflects a scientific approach. The history should suggest a number of possible disorders that might explain the symptoms and course of illness (see Chapter 32).
- The history includes the child's current general health, medical health history, developmental history, and family medical history.
- Attention to a family history of cardiac, endocrine, psychiatric, or neurological illness is pivotal.

The physical examination

All physicians must be aware that a physical examination can affect the patient and family in many ways. Those who see children should be particularly attuned to how pediatric patients may perceive the examination. Most children and adolescents think that psychiatric care, which focuses on mood, “feelings,” and behavior, is fundamentally different from pediatric health-care, which focuses on general health (well child care), infections (e.g., colds, flu, otitis), or injury. Patients may be surprised that the psychiatrist will be examining them. In addition, for many children, the mind and the body are such separate entities that if the child is not in physical pain, the logic of performing a physical examination will be obscure. They may not understand intuitively how a problem affecting their thinking, mood, or behavior would have any connection with their body.

The physician must also be aware of and protect the patient’s modesty and anxiety. Thoughtfulness about modesty makes it imperative that a parent (or guardian) and/or another health-care provider be with the physician at all times during the physical examination. Physicians should refrain from physical contact whenever they are alone with their patients. The rationale for keeping this boundary includes therapeutic, psychological, ethical, and legal principles.

This awareness should also lead the physician to help the patient understand what will be done and why. One cannot assume that all children will understand and interpret the physician’s intentions correctly. Explaining what will be done before doing it allows anxious or confused children to anticipate the procedures of the examination and to see the point of the doctor’s requests. Furthermore, compared to healthy children, children with severe psychiatric disorders have a greater risk of misunderstanding physical interactions. There also may be cultural beliefs about physical contact to consider when examining a child and these should be raised and discussed with the parent(s) in advance.

The physician must also be aware of how developmental features come into play when examining a child. Creating an environment in which a child can ask questions and exercise some choice over the examination is important. The space used for the examination should be well lit, large enough to move around comfortably, and protect privacy. Part of the art of examining developmentally younger children is gathering neurological information from observations while the child is engaged in ordinary actions or playing simple games. For a child with a psychiatric disorder, the examination will be less invasive and distressing when one uses techniques that include toys, observations, and games, rather than simply running through a series of requests to perform movements or actions.

As generally described in the introduction, the decision about who should examine the child will depend on the circumstances and the context of that child’s general health care. When a child has an established pediatric care provider, the onus falls on the doctors to reach a mutual decision about who will

perform the examination. In some cases, it is desirable for each doctor to perform some segments of the examination. For children who are being seen for psychiatric care, the mental status/neurological examination is the principal focus and attention is given to other sections of the physical as dictated by additional signs and symptoms (e.g., sign of encephalopathy, dysmorphic features, intellectual disability). In other circumstances, such as when a child is admitted to an inpatient or intensive psychiatric care facility or there are no other medical care providers available, a psychiatrist may do the entire physical examination.

There are excellent texts available for methods and techniques of the physical examination (e.g., LeBlond *et al.*, 2008; Bickley, 2012). A complete review of techniques and methods exceeds the scope of a single chapter of guidelines. Generally, practitioners have a standard, systematic, highly practiced routine for performing the examination. Nevertheless, some areas encompass findings that deserve comment because of their relevance for child psychiatric assessment. While few symptoms are pathognomonic of any disorder, the presence of a physical sign will raise hypotheses about possible underlying disorders, any one of which can be confirmed or refuted by the pattern of additional findings.

By convention, the examination typically begins with obtaining vital signs. The patient’s height, weight, blood pressure, and pulse are important baseline measures. It is quite important for physicians to plot height, weight and head circumference on a growth chart so that this can be tracked over time. Vital signs assume even more salience when one is considering pharmacological interventions that might affect weight or cardiovascular function. When vital signs fall significantly above or below the normal range, this may signal the presence of a variety of medical and/or psychiatric conditions. For example, acquired low weight could reflect the presence of protein-calorie malnutrition, an eating disorder, depression with loss of appetite, hyperthyroidism, celiac disease, anemia, cancer, or another primary medical condition. As part of obtaining such data, careful attention also is needed regarding the child’s growth. Signs of alteration in height or weight can provide clues to various changes in the child’s medical well-being. In addition, some medications, such as SSRIs or psychostimulants, can alter the child’s growth. As a result, it is important to be aware of the child’s current growth trajectory when initiating treatment.

Plotting the patient’s weight using standard growth charts will also assist physicians in recognizing excessive weight or obesity. When obesity is found, the risks to psychological and physiological health should be reflected in the history, physical examination, and any laboratory/medical tests that the physician considers and monitors. Obesity carries risks for psychopathology (Swallen *et al.*, 2005) and may generate sleep apnea, which, in turn, may produce or exacerbate psychiatric symptoms (Sateia, 2009).

The examination of the skin, which includes lesions, skin texture, and color variations, can reveal systemic illness or signal the presence of noteworthy behaviors. Common skin lesions, such as scars may also be informative and reflect intentional self-injury, repeated accidents, or past physical trauma (e.g., abuse). Acne, while very common, may be a notable source of distress, particularly among socially anxious adolescents. Skin hygiene could suggest loss of self-care or parental neglect, particularly when accompanied by parasitic infections such as lice and scabies. The skin also may show active lesions resulting from picking (dermatotillomania), pinching (tics), abrasions (from compulsive behaviors), petechia (especially around the eyes suggestive of self-induced choking), abuse (welts, bruising, petechia in specific patterns such as grip marks or ligatures, burns, wounds) or self-inflicted wounds. Examination of hair distribution and texture may reflect systemic illness or trichotillomania. The skin examination may also show dramatic hair styles, skin piercings, and tattoos that while not pathological, open avenues to learn about the patient's life, interests, and relationships.

Abnormalities in skin and hair texture could point to thyroid disease as a contribution to depression or cognitive changes.

Areas of hyperpigmentation may suggest neurocutaneous disorders that correlate with central nervous system disease such as neurofibromatosis. Examination of facial skin may reveal other neurocutaneous disorders such as Sturge Weber syndrome or tuberous sclerosis that carry risks for disruptive/mood disorders (Chapieski *et al.*, 2000) and autism spectrum disorders (Numis *et al.*, 2011), respectively.

The head, eyes, ears, nose, and throat examination bundle a number of signs that can be psychiatrically important. Head shape can reflect environmental risks from neglect or genetic risks from craniosynostosis (Speltz *et al.*, 2004), particularly in intellectually disabled children. Head circumference, like other physical measures, may be excessively large or small and suggest genetic and neurological disorders with behavioral features. Similarly, highly characteristic dysmorphic facial features may suggest specific genetic disorders such as trisomy 21, Fragile X, Prader-Willi, Angelman, Klinefelter, Velo-cardio-facial (VCF), Williams, or Turner syndrome. There is a wide range of facial abnormalities in VCFS but cleft palate, particularly involving the soft palate, and elongated face, wide nose, and small ears are frequently seen with this disorder. Characteristic facial features are also seen with repeated fetal exposure to alcohol. Deprivation or neglect may lead to poor dental hygiene and severely damaged teeth and gums that are observed on examination of the mouth and throat. Inspection of the mouth can also reveal signs of self-induced vomiting, such as erosion of teeth and lesions in the mouth. Lesions from sexually transmitted diseases may be visible. Examination of the appearance of the eyes may uncover disorders affecting genetic/metabolic (e.g., Wilson's disease, neurofibromatosis) or endocrine (thyroid) function. Systemic and infectious diseases can influence eye function such as pupillary responses to light and accommodation.

A quick examination of vision may be conducted by having the patient view a hand-held pocket vision screener (or an E-chart) card at 14 in. or 36 cm, or copy drawings of familiar geometric shapes. Disorders that produce dysmorphic facial features like those mentioned could affect the shape, size, and placement of the ears. Limited or loss of hearing affects language acquisition in young children. Any concerns about hearing should be assessed by an audiologist, but a screening assessment can be performed in a quiet room by asking if the child can hear the sound of the clinician rubbing a forefinger and thumb together at a distance of about 13–14 in. (or 35–36 cm) from the ear.

Pediatric psychiatric disorders have many fewer specific associations with examination of the neck, heart, lungs, and abdomen. One major exception is the size of the thyroid gland, and, in asthmatic children, the presence of wheezing. Genetic disorders like the ones noted, may affect cardiac hemodynamics and auscultation.

The circumstances that require a psychiatrist to perform a genital examination are rare. It is generally recognized that psychiatric care providers should refrain from genital examinations. When other features of the physical examination suggest a pattern that requires inspection of the genitals in order to winnow the differential diagnosis (such as Fragile X, Klinefelter, or Prader-Willi syndrome, or disorders of sexual development), arrangements for another provider to perform a genital examination should be made. If it is necessary, such an examination demands the utmost of attention to the patient's comfort and modesty. Unless there are extraordinary circumstances, one should never examine a patient's genitals without a parent/guardian being present. If a genital examination is essential, the psychiatrist must explain and give a clear rationale for it in advance.

The examination of the extremities may reveal picking, bruising, scarring or recent evidence of self-injury. Much less commonly, one may see signs of dysmorphology in the extremities or back that suggest genetic disorders with psychiatric manifestations such as Smith-Magenis Syndrome (Gropman *et al.*, 2006). Also, disorders such as Prader-Willi Syndrome (Kroonen *et al.*, 2006; Cassidy *et al.*, 2012) or XXX syndrome (Otter *et al.*, 2010) may produce scoliosis and are associated with psychiatric symptoms.

The neurological examination is highly relevant to child psychiatric care and to resolving hypotheses about the diagnosis (see Chapter 32). Many pediatric neurological conditions produce psychiatric symptoms; discussing each of them exceeds the scope of this chapter. However, physicians should be mindful of behavioral and emotional changes that may be the first sign of a progressive neurological condition. The neurological examination should assess the cranial nerves, motor system (strength and tone), sensory system, balance and coordination, reflexes and mental status. Particular attention should be paid to sudden changes in cognitive and emotional functions since these may

signal progressive and acute conditions (Wilne *et al.*, 2006; Reulecke *et al.*, 2008). A great deal can be learned by carefully observing the patient during an ordinary interview or, with younger children, while playing age appropriate games such as throwing or kicking a ball. Fine motor coordination skills can be observed from playing a game of copying geometric figures or simply asking the child to make a drawing. How the child walks, gets up from the floor, or moves during conversation can provide leads for a more focused examination. Observing repetitive movements, mannerisms, voice quality, articulation, gait, gaze, and coordination can be accomplished during a typical interview.

The mental status examination is central to the child psychiatric examination. The basic elements of the mental status examination focus on the patient's capacities and current function in the context of their developmental level. As with the examination of adults, the mental status examination begins with the patient's appearance, mood, and affect. The clinician notes the variations and range of mood and affect during the interview. Inquiring about current or past suicidal ideation or thoughts/plans to harm others should be a routine part of the examination. Observations are made of the patient's speech and language. Behaviors are noted including stereotyped motor movements, capacity to sit calmly, and use of nonverbal communication such as gestures, facial expressions, and eye gaze. Changes in behavior during the interview are important, too. Cognitive capacity can be estimated from the patient's vocabulary, the coherence of the patient's ideas, and complexity of the patient's language construction. The child's narrative provides information on major themes and contents of the patient's thoughts. Spontaneous comments convey information about the flow of the child's thoughts and whether there is perseveration, developmentally immature thinking, frankly odd or bizarre ideas, or reason to have concerns about delusional beliefs, hallucinations, or perceptual distortions. When considering the presence of hallucinations, it is important to inquire whether they arise exclusively in a pattern of falling off to sleep (hypnagogic) or upon awakening from sleep (hypnopompic). It is also useful to learn whether they are vivid, frightening to the child, can be summoned or dismissed easily, and if the child is convinced they are caused by an outside source rather than his or her mind (Pilowsky & Chambers, 1986). A great deal about the patient's mental status can be learned from ordinary conversation. Features of orientation, mood, affect, intelligence, fund of knowledge, judgment, memory, attention, and abstracting abilities can be readily noted. When a child performs well academically without accommodations at school, this usually reflects at least average general intelligence. The mental status examination traditionally includes comments on the manner of the child's relating to the examiner over the course of the interview(s) and on any changes in that manner of relating with time and topics.

Summary key points of the physical examination

- Performing a physical examination is basic to a comprehensive understanding of the patient.
- Sensitivity to the patient's past experiences, current state, culture, and developmental and cognitive levels should be foremost.
- Protecting the patient's modesty and providing reassurance by explaining what will be done before doing it are key.
- Components of the physical examination that require touching the patient should be performed while the parent/guardian is present.
- The physical examination includes vital signs and follows with a systematic approach for each segment of the body.
- It is generally recognized that psychiatric care providers should refrain from genital examinations.
- The neurological and mental status examinations are pivotal for a child psychiatry physical examination.

Laboratory investigation

The laboratory investigation flows from the same rubric as the physical examination. The physical examination is guided by thoughtfully listening to the chief complaint, being alert to any patterns that emerge as one hears about additional symptoms, narrowing the range of possible conditions to a differential diagnosis, using observation and examination to further narrow the possibilities, and ultimately gauging the likelihood that a condition is contributing to the child's impairment. The laboratory investigation provides additional data to support or refute the diagnostic possibilities that are raised by the history and physical examination. The decision about which additional studies to pursue should grow out of consideration of the context of the child's usual healthcare, the hypotheses about the most likely conditions, and clinical judgment about whether there may be an acute problem that poses immediate risk. Figure 35.1 offers an example of this kind of deductive process. There are risks and problems that arise from obtaining laboratory data using a scattershot approach that ignores the foundations of a considered differential diagnosis.

Under the optimal circumstances a child will have regular healthcare and will have been followed by a pediatric or family medical doctor. If so, the physicians should confer, discuss possible medical contributions to the patient's symptoms, and come to a consensus about the need and direction for any laboratory workup. Typically the laboratory evaluation will be the purview of the care provider who oversees the child's general medical health. As with the physical examination, the decision about who should order and follow the laboratory investigation and tests will depend on the circumstances and the context of that child's general health care. However, there may be suboptimal circumstances or extenuating situations that

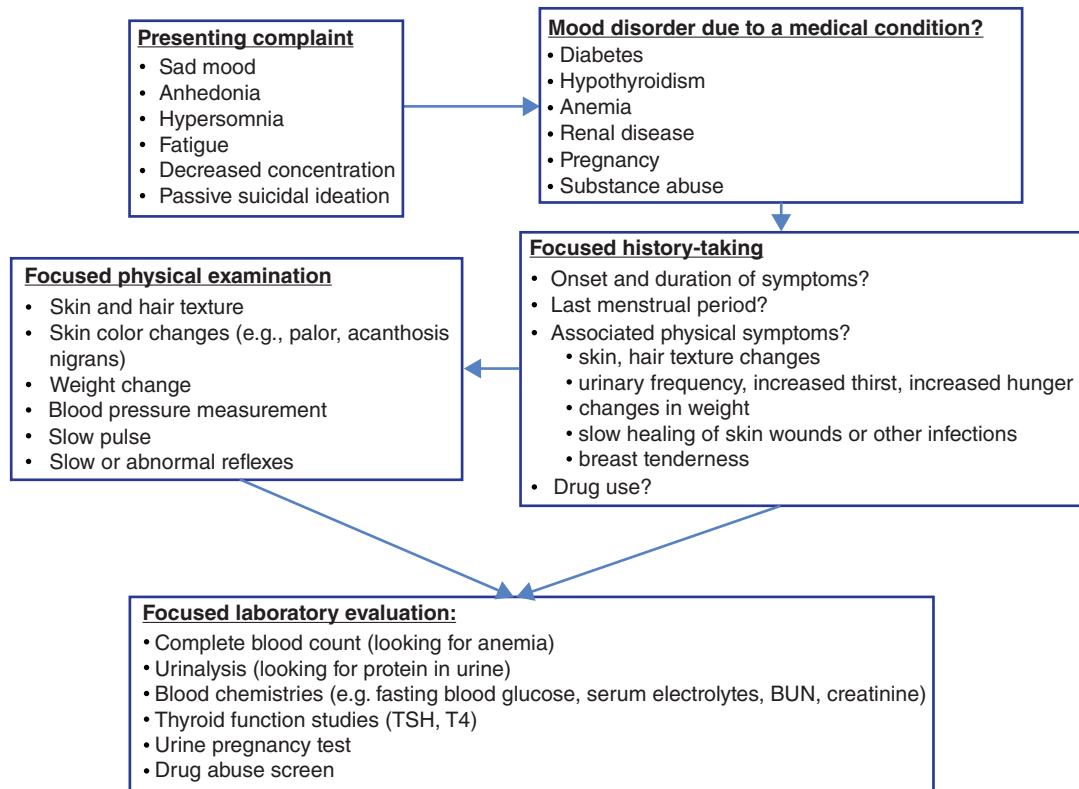

Figure 35.1 Medical assessment of a 16-year-old female with “possible depression.” BUN, blood urea nitrogen; TSH, thyroid-stimulating hormone.

shift the responsibility to the psychiatrist. If so, then one should think about the medical evaluation as composed of steps and consider what a subspecialist might need in order to proceed subsequently with a more focused and specific evaluation. For example, if following considerable weight gain there were concerns about fatigue, polyuria, persistent thirst, and increased appetite, then the psychiatrist might obtain a fasting blood sugar, glycosylated hemoglobin level (HbA_{1c}), and, if possible, an oral glucose tolerance test before referring the child to a diabetic subspecialist (Copeland *et al.*, 2013).

The attuned clinician will also consider the impact that laboratory procedures have on the patient. On casual consideration, phlebotomy, an ECG, or an electroencephalogram (EEG) might seem minor, but these procedures can make children highly anxious. Therefore, it is important to explain, in developmentally informed terms, what will happen and why.

The timing of these laboratory studies is relevant. The laboratory evaluation may unfold over time as initial findings raise questions that need additional studies for answers. Also, the impact on parents of requesting these studies should be considered. In some situations, laboratory results may be needed urgently, but others may be deferred. Thought should be given to who will need the results and efforts should be made to avoid unnecessary repetition of studies. For example, if a child

has abdominal pain that could be due to gastro-esophageal reflux or anxiety, one might defer a medical workup (when the patient has relatively easy access to healthcare providers) until a pediatrician or family medical doctor has seen and examined the patient.

There is no standard battery of laboratory tests for psychiatric disorders and laboratory studies should never be ordered simply to assess “general health.” However, when one suspects the presence of a specific condition, a focused laboratory assessment should be performed. For example, if there are concerns about anemia or bleeding problems then obtaining a complete blood count with differential count, hemoglobin, hematocrit, and coagulation indices such as a prothrombin time and partial thromboplastin time are warranted. If one is starting medications that might worsen anemia or bleeding, it would be important to obtain premedication, baseline measures. For example, SSRIs may cause changes in coagulation and, rarely, anemia, and therefore a full blood count (or a complete blood count in the United States) with differential count could be a reasonable baseline study to obtain.

Where the history suggests recurrent infections, symptoms of neurological problems with weakness and/or coordination, and weight loss, the physician might pursue whether there has been exposure to human immunodeficiency virus (HIV). Under these

circumstances, or in parts of the world where the virus is highly endemic, HIV testing is warranted. In some parts of the world, this is standard testing for anyone admitted to hospitals or residential care facilities.

There is no standard battery of laboratory tests that must be obtained for all psychotropic medication. The selection of the tests and recommendations for ongoing monitoring will depend on the agent and other risk factors that individual patients bring to treatment. Generally, the laboratory tests and monitoring follow from the “Warnings” or “Warnings and Precautions” sections of the package insert or drug information for each specific agent. These sections typically recommend screening procedures, risks of concomitant medications, as well as clinical signs and symptoms that should be monitored. They often include what tests should be obtained.

Fortunately, most children have healthy kidney function. But if there are concerns about kidney impairment, or if one is starting a drug that is primarily excreted through the kidneys such as lithium, then obtaining a serum creatinine level, blood urea nitrogen, and basic electrolytes (sodium, potassium, chloride, carbon dioxide) would be important. Also, basic urine analysis would allow one to know whether there is proteinuria, any evidence of infection, or presence of particular metabolic conditions.

Primary liver disease is rare in children. However, since many medications can affect liver function, obtaining liver function tests becomes important prior to starting some medications. Generally liver function tests include alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and measures of direct and indirect bilirubin. Since high rates of hepatitis are to be found among children in some locales, results of these indices might lead one to proceed with obtaining measures of serum hepatitis antibodies.

Similarly, when there are concerns about cognitive function along with attentional problems and disruptive behaviors in a child who resides where environmental conditions produce a high risk of exposure to lead, one might obtain a serum lead level. The need for this would be more compelling if the child was young and had not had a lead level measured at any earlier point, or at any point while residing at his or her current address.

The decision to obtain thyroid function studies should be based on the examination (e.g., thin hair, puffy face, dry skin, bradycardia, muscle weakness) and symptom profile (depression, constipation, fatigue, cold sensitivity, impaired memory). However, even if there are fewer suggestive symptoms, a child who resides in a region where iodine deficiency is endemic (such as mountainous regions, areas of the northern Ganges River (India), or in North Africa) gives one more impetus for obtaining thyroid-stimulating hormone (TSH) and thyroxine (T4) (Zimmerman, 2009).

When considering additional medical studies, such as an ECG or EEG, the indications should be clear. Some medications, such

as atypical antipsychotic medications or noradrenergic antagonists, may change cardiac conduction. Therefore, it is prudent to obtain a baseline ECG prior to starting these agents and to observe for any changes as the dose is increased. This is particularly important in children who have a family history of sudden death in young relatives, have a family history of cardiac anomalies or conduction disorders such as Wolff–Parkinson–White syndrome, or have a personal history of symptoms such as syncope, severe shortness of breath during exercise, prolonged or very significant fatigue, or, on routine ECG, borderline cardiac indices. This also is important when considering use of stimulant medication. The increase in pulse, blood pressure and cardiac work that methylphenidate or dextro-amphetamine produce, or direct cardiac conduction effects that agents like atomoxetine might induce, could exacerbate occult underlying cardiac problems (Stiefel & Besag, 2010; Martinez-Raga *et al.*, 2013). In addition, children with known cardiac anomalies may be more likely to have symptoms of inattention, restlessness, and impulsivity, making them at particularly high risk for developing side effects when treated with these agents.

The decision to obtain an EEG should follow from the history and any symptoms that have been observed. The yield of clinically meaningful information from routine EEGs in children with generic psychiatric disorders is low (Camfield & Camfield, 2000; Smith, 2005; Raybould *et al.*, 2012) and does not offset the cost, inconvenience, and discomfort to the patient. Conversely, when there is a history of paroxysmal events, with motor and/or psychomotor events, a prior history of serious head injury, the presence of disorders with a high likelihood of comorbid epilepsy, such as intellectual disability, specific genetic disorders, or autism spectrum disorders, then there is a compelling case to be made for obtaining an EEG. It is useful to pursue a careful history for any stereotyped symptoms that precede the psychomotor events or any “post-ictal” symptoms such as fatigue, cognitive dulling, or confusion that typically follow the event. Similarly, any disorder that presents with a decline in, or loss of previously acquired skills warrants an evaluation that includes an EEG.

The likelihood of finding clinically useful information from routine neuroimaging of child psychiatric patients is low. This is discussed thoroughly in Chapter 11. At this point there is a limited role for neuroimaging in general child and adolescent psychiatry.

Similarly, there is a very limited role for routine genetic evaluations. There are circumstances when the physical examination or concerns about intellectual disabilities (see Chapter 54) may require obtaining chromosomal and/or genetic studies. In addition, in the future, there may be a role for obtaining genetic studies when the patient gives a personal or family history of adverse drug reactions that raise a possibility of hyper- or hypo-metabolism of specific agents (e.g., codeine) (Kuehn, 2013). However, obtaining genetic assessments as a routine part of an evaluation is premature now. This is a controversial

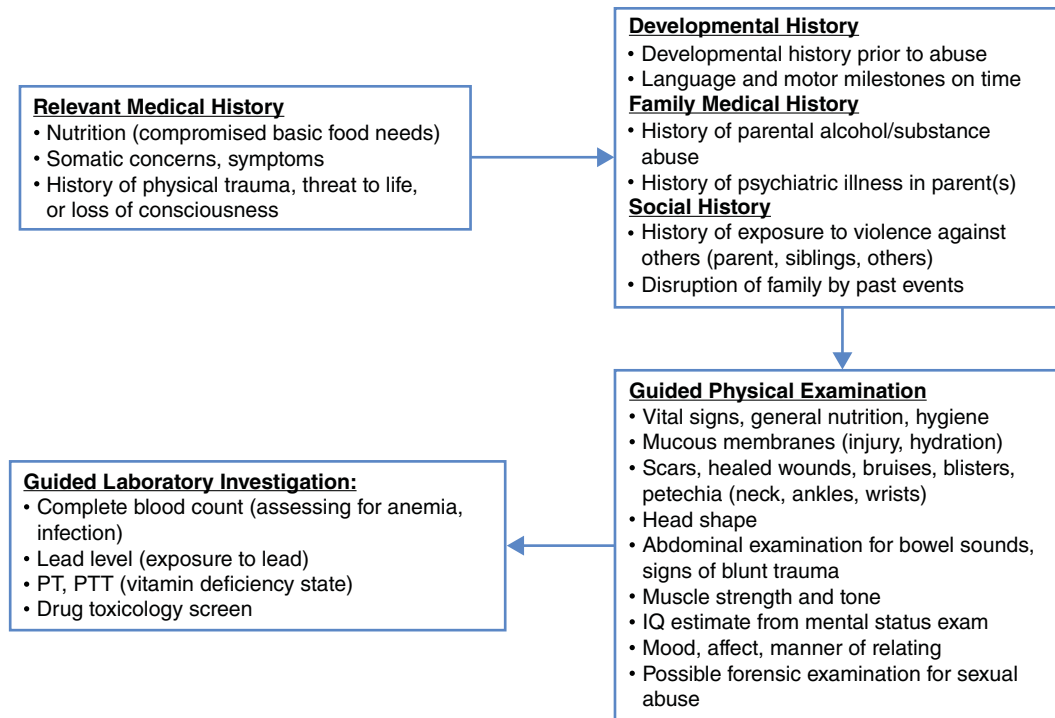

Figure 35.2 Medical assessment of an 8-year-old female with “possible post traumatic stress disorder,” recently removed from an abusive/neglectful home. PT, prothrombin time; PTT, partial thromboplastin time.

area with proponents who recommend genetic studies to guide selection of pharmacological agents (Wall *et al.*, 2012).

Assessment of cognitive functions should also flow from the history and physical examination. The history may point to consistent problems with learning and/or reaching social and cognitive milestones. This would prompt the clinician to consider obtaining a standard assessment of intellectual function (see Chapter 54). Similarly, specific patterns of impairment may emerge from the history, or arise from interviewing the child. A review of the child’s academic history will provide essential data when considering the need for subsequent evaluations. Specific impairments in receptive language (e.g., problems with understanding instructions or explanations that use simple vocabulary), word finding, expressive language (e.g., problems in expressing thoughts, using appropriate length of utterances, using age- and culturally-appropriate vocabulary), or organization of language would prompt one to obtain a focused evaluation of language function from a speech pathologist (see Chapter 52).

Two examples of the flow of information and what the physician might consider during the examination are offered (Figures 35.1 and 35.2).

An example: the evaluation of psychosis

The differential diagnosis of psychotic conditions in children and adolescents is extensive (see Chapter 57; Yudofsky & Hales, 2007; Lishman’s Organic Psychiatry (Anthony *et al.*, 2012).

The general grouping of etiologies parallels the many causes of delirium and mental status changes in adults (Table 35.1). In approaching the evaluation of the patient with new-onset psychosis, the psychiatrist must place particularly strong emphasis on the history, examination, and presentation of symptoms.

Despite the long list of disorders in Table 35.1, the probability that a child will have any one of these conditions is less than 1–2/10,000. For this reason, the preliminary laboratory examination should proceed from the presence of additional signs or symptoms. Laboratory assessments should also consider the most common etiologies first. For acute onset psychoses, it is reasonable to begin with a drug screen, complete blood count with differential (to consider infectious etiologies), serum electrolytes, urine analysis (for specific gravity, glucose, drugs of abuse, porphobilinogen, infection), thyroid function studies, and, if there are neurological symptoms or history that denote lead intoxication or seizures, a lead level, and an EEG.

Summary key points of the laboratory investigation

- The laboratory investigation provides additional data to narrow diagnostic possibilities raised by the history and physical examination.
- The decision about which additional studies to pursue considers the context of the child’s usual healthcare, the hypotheses about the most likely conditions, and clinical judgment about whether there may be an acute problem that poses immediate risk.

- There is no standard battery of laboratory tests for psychiatric disorders and laboratory studies should not simply assess “general health.”
- When one suspects the presence of a specific condition, a focused laboratory assessment should be performed.
- Acquiring additional medical assessments such as ECG, EEG, genetics, cognitive testing, and language/communication evaluations follows from the history and physical examination.
- Routine use of neuroimaging in child psychiatry has a low yield of clinically useful information at this point.

Summary

Examination of the child psychiatric patient routinely includes all the basic elements of medical inquiry: the chief complaint,

history of current illness, past medical and psychiatric history, family medical and psychiatric history, and a physical examination. Following the leads from these data, the psychiatrist may confer with a medical provider to plan for focused laboratory and other clinical evaluations that will reduce the differential diagnosis in a logical manner. Generally, that child's medical provider conducts the direct physical examination of the child, but there are occasions and situations when the psychiatrist may be required to examine his or her patient. If so, the sensitivity of the physician to the patient's past experiences, current state, culture, and developmental and cognitive levels should be foremost. The components of the examination that require touching the patient should occur in the presence of a parent or guardian. Perhaps one of the most vital skills in obtaining data from the history and physical examination is the mental health professional's capacity for observation. A great deal can be learned about cognitive and neurological functions from close observation of the patient during interviews, simple requests, and ordinary interactions.

Table 35.1 Differential diagnosis of delirium/psychosis.

I Toxic conditions (such as)	
(a)	Substance abuse (amphetamines, bath salts, cocaine, 3,4-methylenedioxy- <i>N</i> -methylamphetamine (MDMA), hallucinogens)
(b)	Acute lead encephalopathy
(c)	Neuroleptic malignant syndrome
(d)	Drug-induced delirium
II Metabolic disorders (such as)	
(a)	Adrenoleukodystrophy
(b)	GM2 gangliosidosis
(c)	Neimann–Pick disease
(d)	Beta-mannosidosis
(e)	Acute intermittent porphyria
(f)	Homocysteinuria
III Endocrinological disorders (such as)	
(a)	Thyrotoxicosis
(b)	Hypothyroidism
(c)	Addison's disease
(d)	Cushing syndrome
(e)	Hyperparathyroidism
IV Infectious diseases (such as)	
(a)	Viral encephalitis
(b)	Bacterial encephalitis
(c)	Post-infectious encephalitis
(d)	Fungal encephalitis (e.g., <i>Cryptococcus</i>)
(e)	Prion diseases
(f)	Spirochetal infections
V Structural neurological lesions (such as)	
(a)	Temporal lobe glioma
VI Autoimmune disorders (such as)	
(a)	Systemic lupus erythematosus
(b)	Sarcoidosis
VII Paroxysmal disorders (such as)	
(a)	Temporal lobe epilepsy
(b)	Partial complex status epilepticus
(c)	Post-ictal psychosis
VIII Specific genetic disorders (such as)	
(a)	Huntington's disease
(b)	Wilson's disease
(c)	Parkinson's disease
(d)	Fahr's disease

B: Considering and selecting available treatments

CHAPTER 36

Psychological interventions: overview and critical issues for the field

John R. Weisz, Mei Yi Ng and Nancy Lau

Department of Psychology, Harvard University, Cambridge, MA, USA

Psychological intervention has deep historical roots. These extend at least as far back as ancient religious teachings about values for proper living, to Greek philosophers' use of discourse to alter perspectives and sharpen understanding, and to the long evolution of medical science and the healing traditions. Interventions for children and adolescents (henceforth "youths") share these ancient roots, but designation of youth psychotherapy as a distinctive specialty owes much to Sigmund Freud (1856–1939), notably his analysis of the "Little Hans" case of horse phobia and his psychoanalysis of his own daughter, Anna (1895–1982). Subsequent growth of youth psychotherapy was fueled by Freud's intellectual heirs, by the grand theories of personality and development, and by models and methods as different from psychoanalysis as behaviorism and cognitive psychology. By the end of the 20th century, Kazdin (2000) had identified 551 different named therapies used with youths. Of course, many more therapies are used in clinical practice, as hundreds of thousands of unique practitioners shape their own approaches.

While youth psychotherapy practice accelerated quickly over the past century, psychotherapy research developed slowly. In 1952, Eysenck's influential review of adult psychotherapy studies suggested that therapy might be ineffective. Levitt's (1957, 1963) reviews, which included youth treatment, reached a similar conclusion. Since the time of Eysenck and Levitt, youth treatment outcome research has grown more rigorous, and its volume has mushroomed (see Silverman & Hinshaw, 2008; Weisz & Kazdin, 2010).

Studying the effects of youth psychotherapy: methods and findings

Youth treatment effects are often assessed via randomized controlled trials (RCTs), and these RCTs can be pooled and

synthesized within meta-analyses (discussed later). Multiple baseline designs, ABAB (sometimes called "reversal") designs, and other single-subject methods are also useful. These methods (see Barlow *et al.*, 2009; Kazdin, 2011) have been used in diverse treatment situations—such as programs for ADHD (see, e.g., Pelham *et al.*, 2010), studies of intervention for an entire classroom (see e.g., Wurtele & Drabman, 1984), or for only one or two youngsters with a rare condition (e.g., McGrath *et al.*, 1987; Tarnowski *et al.*, 1987). Studies using these designs have produced a rich body of outcome evidence and some meta-analyses—for example, on treatment for disruptive behavior (Chen & Ma, 2007), autism spectrum disorders (Campbell, 2003), and social skill deficits (Mathur *et al.*, 1998). That said, youth psychotherapy meta-analyses have mainly focused on RCTs.

Meta-analytic findings

Among the meta-analyses of youth RCTs, four have synthesized findings from diverse treatments and treated conditions. Casey and Berman (1985) focused on studies with children aged 12 and younger. Weisz *et al.* (1987) included studies with 4- to 18-year-olds. Kazdin *et al.* (1990) included studies with 4- to 18-year-olds. Finally, Weisz *et al.* (1995) spanned ages 2–18. Mean effect sizes found in these four meta-analyses are shown in Figure 36.1, with a comparison to two widely cited meta-analyses of predominantly adult psychotherapy (Smith & Glass, 1977; Shapiro & Shapiro, 1982). The figure shows that youth treatment effect sizes fall mainly within the range found for adult therapy, and on average between Cohen's (1988) benchmarks for medium (i.e., 0.5) and large (0.8) effects.

Two other youth meta-analytic findings sharpen the picture in an encouraging way. First, findings (Weisz *et al.*, 1987, 1995) showed that effects measured immediately after treatment were quite similar to effects measured at follow-up assessments, which

Figure 36.1 Mean effect sizes found in two broad-based meta-analyses of adult psychotherapy effects (the two bars at the left: Smith & Glass, 1977; Shapiro & Shapiro, 1982), four broad-based meta-analyses of youth psychotherapy effects (the four middle bars: Casey & Berman, 1985; Weisz *et al.*, 1987; Kazdin *et al.*, 1990; Weisz *et al.*, 1995), and two meta-analyses of RCTs comparing evidence-based youth psychotherapies to usual clinical care (the two bars at the right: Weisz *et al.*, 2006a, 2013b). The full bar for Kazdin *et al.* (1990) shows the mean effect size for treatment vs. inert control group comparisons; the dashed line shows the mean for treatment vs. active control group comparisons. The full bar for Weisz *et al.* (1995) shows the mean effect size when unweighted least squares analyses were conducted; the dashed line shows the mean for weighted least squares analyses. *Source:* Reprinted with permission from John R. Weisz.

averaged about 6 months after the end of treatment. This suggests reasonable holding power of treatment benefit over time. Second, findings indicated that effects are larger for the specific problems targeted in treatment than for problems that were not specifically addressed (Weisz *et al.*, 1995). This suggests that the tested therapies did not just create nonspecific good feelings but instead impacted rather precisely the kinds of dysfunction they were designed to treat.

These findings suggest certain strengths of youth psychotherapies, but meta-analysis can also highlight challenges, critical questions, and areas in which intervention needs to be strengthened. A meta-analysis of psychotherapy for youth depression, for example, showed beneficial effects that were statistically significant (mean effect size: 0.34) but also significantly smaller than effects of treatments for other youth problems and disorders; even the very popular cognitive approaches, including cognitive behavioral therapy (CBT), were no more successful than alternative treatments in alleviating depression (see Weisz *et al.*, 2006b). Such findings provide a reality check, potentially suggesting a need to strengthen or even reenvision youth depression treatment.

Identifying “evidence-based psychotherapies”

As treatment outcome evidence accumulated over the years, and documentation of the tested treatments grew more precise (typically in the form of detailed treatment manuals), efforts were launched to identify the specific therapies sufficiently well supported to be considered “evidence-based psychotherapies” (EBPs). Task forces and review teams were formed

(see e.g., Chambless *et al.*, 1998) to distill the research evidence and identify therapies that met standards for different levels of empirical support. Building on this work, experts in youth psychotherapy compiled their own reports in two journal special issues (Lonigan *et al.*, 1998; Silverman & Hinshaw, 2008). In the most recent report (Silverman & Hinshaw, 2008), reviewers identified therapies at four levels of empirical support: (1) *well-established* (i.e., two good group-design experiments by different research teams in two different settings, showing the treatment to be “superior to pill, psychological placebo, or another treatment”), (2) *probably efficacious* (i.e., “... at least two good experiments showing the treatment is superior ... to a wait-list control group”), (3) *possibly efficacious* (i.e., “... at least one ‘good’ study showing the treatment to be efficacious in the absence of conflicting evidence”), or (4) *experimental* (i.e., “... not yet tested in trials meeting task force criteria”).

This 2008 report identified dozens of youth psychotherapies as either *well-established* or *probably efficacious*, encompassing multiple disorders and problems. Table 36.1 shows the youth treatments classified at these two highest levels in the Silverman and Hinshaw (2008) special issue. Throughout this chapter, we refer to these interventions as EBPs.

The evidence-based psychotherapies: “well-established” and “probably efficacious” Autism

In the autism review (Rogers & Vismara, 2008), only one treatment was designated well-established: Ivar Lovaas’s Early Intensive Behavioral Intervention (EIBI; Smith, 2010); this is a form

Table 36.1 Evidence-based youth psychotherapies^{a,b}.

Problem/disorder category	Well-established (WE) or Probably efficacious (PE) psychotherapy

^aData source: Silverman, W.K. & Hinshaw, S.P. (eds) (2008) Evidence-based psychosocial treatments for children and adolescents: A ten year update [Special issue]. *Journal of Child and Adolescent Clinical Psychology* **37**, 1–301.

^bThis table shows classifications for broad forms of psychotherapy (e.g., Cognitive behavioral therapy; CBT); some reports in the special issue of the journal also classified specific treatment subtypes (e.g., group CBT for children, individual adolescent CBT plus parent/family component), which are not included in the table, given space limitations.

of applied behavior analysis that entails individual discreet trials training, often 30 hours per week or more, building specific core skills in language, social interaction, self-help, and other domains critical to children's development. Therapists treat the children and train parents to continue the intervention at home.

A related intervention, Pivotal Response Training (PRT; Koegel *et al.*, 2010) was rated probably efficacious; PRT uses core skills of the Lovaas model but with an expanded emphasis on treatment in the child's natural environment and on strategies for boosting the child's motivation to learn (e.g., relying on activities the child

chooses, identifying natural reinforcers). PRT teaches communication, academic, self-help, social, and even recreational skills; like EIBI, PRT relies heavily on training parents to deliver the intervention.

Eating disorders

Only one treatment for eating disorders was identified as an EBP (see Keel & Haedt, 2008): family therapy for anorexia nervosa, and in particular the Maudsley model (Lock *et al.*, 2001). This model includes (a) relying on family members to return the client to more normal eating behavior—a process called “refeeding the client”; (b) negotiating restructured relationships in areas that influence eating behavior (e.g., if deceit is used by the family to avoid conflict *and* by the youth to conceal bingeing, therapy may focus on alternatives to deceit); and (c) termination, including planning ways to sustain healthy eating by sustaining healthy intrafamily relationships and youth autonomy. No EBP was identified for bulimia nervosa in adolescents, but the reviewers (Keel & Haedt, 2008) noted that CBT (e.g., addressing distorted cognitions about body shape and size, using behavioral procedures to structure healthy eating habits) is a well-established treatment for bulimia in young adults and older adolescents. A special challenge in the eating domain is that eating disorders can take multiple forms, and in fact the most prevalent diagnostic category is “not otherwise specified.” Thus, even effective treatments for anorexia and bulimia will not necessarily fit most eating disordered youths (see Chapter 71).

Anxiety disorders

For phobic and anxiety disorders in youth (reviewed by Silverman *et al.*, 2008b), the most thoroughly tested psychotherapies are the CBTs; these most often blend graduated exposure to feared stimuli with efforts to identify and modify distorted cognitions that can spark and sustain fears. The treatments rated as EBPs included individual CBT, group CBT, group CBT with parents, and Social Effectiveness Therapy for Children (SET-C; Beidel *et al.*, 2000). SET-C, designed for social phobia, includes group sessions for youngsters, *in vivo* exposure sessions (e.g., practicing interacting with nonanxious peers), and teaching parents to notice and reward their children’s steps toward less anxious behavior in social situations.

In their review of interventions for obsessive compulsive disorder, Barrett *et al.* (2008) identified only one treatment that met EBP criteria: individual exposure-based CBT. Youths are exposed to stimuli that lead to their obsessive fears but then told not to engage in the compulsive behavior those fears usually trigger. Ideally, across repeated exposures, the anxiety-obsession-compulsion cycle is weakened via autonomic habituation and altered cognition, as youths learn that bad things they fear do not actually happen when they say no to their compulsions.

Finally, reviewing treatments for youths exposed to traumatic events, Silverman *et al.* (2008a) identified trauma-focused CBT

(Cohen *et al.*, 2010) as an EBP. This treatment, designed for young victims of sexual abuse and other forms of maltreatment, uses components of CBT for anxiety, plus additional elements designed to fit the situations in which trauma occurred. The components include, for example, safety planning (to reduce environmental risk) and “trauma narrative,” in which young people write, then read, descriptions of their traumatic experiences. The draft narrative is repeatedly read to the therapist, as a form of exposure therapy. Distorted cognitions in the narrative (e.g., inappropriate self-blame) are modified through discussion between the youth and therapist. Caregivers participate, by joining the youth and therapist at later readings of the narrative and by supporting the youth’s courage in sharing the story. Silverman *et al.* (2008a) also identified school-based group CBT (Kataoka *et al.*, 2003; Stein *et al.*, 2003) as an EBP. This treatment, designed for youths exposed to community violence, includes psychoeducation, cognitive work, coping skills training, social skills training, and graduated exposures carried out through writing and/or drawing.

Depression

David-Ferdon and Kaslow (2008), reviewing depression treatments, identified two broad approaches as EBPs: Interpersonal Psychotherapy for Adolescents (IPT-A; Mufson *et al.*, 1999) and CBT. IPT-A focuses on interpersonal issues that are common among adolescents, such as the ways roles shift in the parent–teen relationship as teens mature; the intervention focuses on helping adolescents build effective strategies for dealing with role transitions, disputes, grief, and interpersonal deficits. As for CBT, its content varies across programs, but it typically includes such components as identifying and scheduling mood-boosting activities, identifying and modifying unrealistic negative thoughts, self-calming and relaxation, and building problem-solving skills. An approach called “behavior therapy” was also identified as a probably efficacious EBP (e.g., Kahn *et al.*, 1990); its contents resembled CBT in most respects.

Attention deficit/hyperactivity disorder

Pelham and Fabiano (2008), reviewing treatments for ADHD, identified three as well-established. One was behavioral parent training, in which parents learn techniques for effective behavior management (e.g., clear instructions, differential attention for desired versus undesired behavior, use of praise and reward, time-out). The second was behavioral contingency management in classrooms, often carried out by school personnel. The third was intensive peer-focused behavioral interventions in recreational settings. A model program of this type is Pelham’s Summer Treatment Program (Pelham *et al.*, 2010), in which youngsters are immersed in sports, academic, and social skill-building activities, all within the context of a highly structured environment with clear behavioral contingencies; caregivers also participate, learning effective behavior management strategies for use at home. Importantly, Pelham

and Fabiano did not find convincing support for CBT or nonbehavioral treatments for ADHD youths.

Conduct-related problems and disorders

In the review of treatments for conduct-related problems and disorders, Eyberg *et al.* (2008) identified 16 EBPs. These included behavioral parent training programs, some involving parent management training (Forgatch & Patterson, 2010; Kazdin, 2010; Sanders & Murphy-Brennan, 2010) and some involving coaching during actual parent–child interactions (e.g., McMahon & Forehand, 2003; Zisser & Eyberg, 2010). The Incredible Years program (Webster-Stratton & Reid, 2010) includes a behaviorally oriented video-guided series involving group sessions for parents (who view and discuss video clips illustrating effective and ineffective parenting strategies), and social skills and problem-solving training groups for children (ages 3–8); the parent and child programs have been shown to be beneficial separately and in combination. Other EBPs for conduct problems include behavioral and cognitive training to enhance anger management (Lochman *et al.*, 2010), problem-solving skills (Kazdin, 2010), and socially appropriate assertiveness (Huey & Rank, 1984), as well as a school-based program designed to reduce misbehavior by training youths to make accurate appraisals of the self and social situations (Block, 1978).

Finally, two of the EBPs identified by Eyberg *et al.* (2008) blend behavioral training for caregivers with strategies for building support within the youth's social system. These include the extensively studied Multisystemic Therapy (MST; Henggeler & Schaeffer, 2010), developed originally for delinquent youths but later extended to other forms of dysfunction (e.g., sexual offending, suicidal behavior), and Multidimensional Treatment Foster Care (MTFC; Smith & Chamberlain, 2010), designed to support effective care for disruptive youths who have been placed in foster care. We later discuss MST and MTFC in greater detail.

Adolescent substance abuse

In their review of treatments for adolescent substance abuse, Waldron and Turner (2008) reported that interventions qualifying for EBP status have focused mainly on alcohol and marijuana use. The three EBPs they identified use a blend of behavioral methods, family systems work, and outreach to broader social systems. One of the EBPs, Functional Family Therapy (FFT; Alexander & Parsons, 1982), relies on core behavioral techniques and a family systems orientation to establish new patterns of family interaction, and therapists also work with extrafamilial systems such as schools and probation offices to help ensure that benefits will generalize to the community. In addition, both individual and group CBT approaches (see Waldron & Kaminer, 2004) were identified as EBPs. In general, the CBT approaches focus on identifying and modifying distorted cognitions, plus training and practice in the behavioral coping skills needed to avoid substance use (e.g., coping with cravings, resisting social pressure to get high, and avoiding situations where substance use might be likely).

Investigating the strength, causes, and conditions of effective treatment

Initially, researchers were most interested in identifying which psychotherapies work. Over time, however, interest has grown in *how* treatments work (i.e., through what processes), *with whom* they work, and *under what conditions*—questions to which we now turn.

Mediators and mechanisms of change

Understanding how a treatment works requires identifying mechanisms of change, the specific processes through which the treatment produces outcomes. A sound understanding of these mechanisms could help treatment developers strengthen the active ingredients of psychotherapy and minimize inactive components, thereby increasing treatment efficacy and cost-effectiveness (Kraemer *et al.*, 2002). A first step in identifying change mechanisms is testing whether a particular variable is a mediator of treatment outcome in an RCT, that is, an intermediate variable evident during treatment that statistically accounts for the treatment–outcome relationship (Kraemer *et al.*, 2002; Kazdin, 2007).

Moderators of treatment outcome

Understanding with whom treatments work and under what conditions requires identifying moderators of treatment outcome. In an RCT, a moderator is a variable present prior to randomization that interacts with treatment condition, such that treatment effects depend on the level of the moderator (Kraemer *et al.*, 2002). Identifying client characteristics that moderate treatment effects can reveal which client subgroups benefit most, and least, from various treatments. That information could help inform clinicians' efforts to identify the best-fit treatments for specific subgroups of patients (Kraemer *et al.*, 2002).

Mediators of evidence-based psychotherapies

To illustrate the search for mediators, we focus here on research testing two variables frequently studied in RCTs of youth EBPs—negative cognitions and parenting practices.

Negative cognitions

Negative cognitions have often been tested as candidate mediators of EBPs for internalizing disorders. This reflects the CBT theoretical model, which holds that symptoms can be reduced by changing cognitions that are unrealistically negative to cognitions that are more positive, realistic, or adaptive.

Mediation tests within RCTs of CBT for youth depression have yielded mixed findings. Shifts to less pessimistic or more optimistic explanatory styles have been found to mediate reductions in children's depressive symptoms (Jaycox *et al.*, 1994; Yu & Seligman, 2002). Decreases in negative automatic thoughts and in dysfunctional core beliefs were significant mediators in some RCTs of CBT for adolescent depression, but not in others (Ackerson *et al.*, 1998; Kaufman *et al.*, 2005; Stice *et al.*, 2010).

There have been fewer studies of mediation in CBT for youth anxiety. However, the studies have rather consistently found that decreases in anxious self-statements mediate reductions in anxiety symptoms in individual CBT (Treadwell & Kendall, 1996; Kendall & Treadwell, 2007) and group CBT (Lau *et al.*, 2010).

Parenting practices

Parenting practices have often been tested as mediators of EBPs for externalizing problems. Most such EBPs aim to reduce youth problems partly through changing their caregivers' behaviors. These EBPs include behavioral parent training for mild conduct problems, MTFC and MST for severe conduct problems, MDFT for adolescent substance abuse, and behavioral treatment for ADHD.

Effective, consistent parental discipline has been found to mediate treatment effects on child conduct problems in RCTs of Parent Management Training—Oregon model (PMTO; Amlund Hagen *et al.*, 2011) and anger control training (Lochman & Wells, 2002). For MTFC and MST—EBPs for adolescent offenders—mediators include not only caregivers' disciplinary practices, but also their ability to limit adolescents' association with deviant peers (Eddy & Chamberlain, 2000; Henggeler *et al.*, 2009). Both caregiver supervision and positive caregiver–youth relationship were also significant mediators of MTFC (Eddy & Chamberlain, 2000). In contrast, caregiver supervision and caregiver–youth communication were not mediators of MST (Henggeler *et al.*, 2009), and family cohesion was not a mediator of PMTO (Amlund Hagen *et al.*, 2011).

For substance use problems, parent monitoring of adolescents' activities and peers has mediated the effects of MDFT, relative to peer group intervention, on adolescents' 12-month abstinence from substance use (Henderson *et al.*, 2009). Intriguingly, mediation was found only when the outcome measured was the proportion of abstinent youths, but not when substance use frequency was the outcome; the authors concluded that parent monitoring may work when it prevents, but not when it merely reduces, substance use. Improved parent–adolescent relationship was not a mediator (Henderson *et al.*, 2009).

Research on ADHD intervention in the Multimodal Treatment Study of Children with ADHD (MTA; MTA Cooperative Group, 1999) has identified parents' discipline practices as a mediator. In the MTA, medication (methylphenidate, Ritalin) only and combined medication and behavioral treatment (i.e., behavioral parent training, summer treatment program, and behavioral classroom management) outperformed behavioral treatment only, as well as community care. Curiously, discipline practices mediated treatment effects on children's social skills at school only when combination treatment—but not behavioral treatment or medication only—was compared to community care; other parenting practices (i.e., positive involvement, deficient monitoring) were not mediators (Hinshaw *et al.*, 2000).

Discussion

The mediation research reviewed may shed some light on the EBPs' potential mechanisms of change. However, many

questions remain. First, the small number of published mediation studies raises a concern that some of the mediators identified may represent chance findings, with many unpublished null findings languishing in file drawers. More replications are needed to confirm that even our best-supported candidate mediators, negative cognitions and parenting practices, are in fact robust mediators of EBP effects.

Second, findings were mixed; for example, negative cognitions did not consistently mediate CBT for depression, and parenting practices other than caregiver discipline did not consistently mediate EBPs for conduct problems. It is not clear whether these mixed findings reflect methodological artifacts, failure to differentiate related but distinct mediators, or true mediators that emerge only for certain conditions, age ranges, symptom severity, problem type, or protocol used; if so, this would represent what is called *moderated* mediation.

Third, we have not found clear evidence that change in any mediator preceded change in outcome; that temporal sequence is necessary for a mediator to be considered a true mechanism of change (Kazdin, 2007). Many studies measured the mediator and outcome at pre- and posttreatment only, precluding efforts to clarify the temporal sequence. For example, Hinshaw and colleagues (2000) could not determine whether combination treatment of methylphenidate plus behavioral therapy in the MTA (a) reduced parents' ineffective discipline, which in turn improved children's social skills; (b) improved children's social skills, which in turn led parents to reduce ineffective discipline; or (c) changed something else that caused improvement in both child social skills and parent discipline. Some (e.g., Henderson *et al.*, 2009) have demonstrated that an earlier measurement of change in the mediator predicted a later measurement of change in outcome, but a mediator change that was *measured* earlier does not equate to a mediator change that *occurred* earlier. Frequent measurement of *both* candidate mediators *and* outcomes throughout and after treatment will be needed to determine which changes occur in which order (Kazdin, 2007). When Stice and colleagues (2010) attempted such frequent measurement, they identified a paltry 8% of participants who met the temporal precedence criterion.

Fourth, a number of variables that have been conceptualized as change mechanisms have rarely been studied as mediators. Mediation studies of youth CBT have generally focused on cognitive variables, not behavioral variables such as engagement in pleasant activities or exposures, which are major components of CBT for depression and anxiety respectively (for exceptions, see Kaufman *et al.*, 2005; Stice *et al.*, 2010). In addition, mediation studies of EBPs for externalizing disorders have often neglected youth cognitive and behavioral variables such as hostile attributions, expectations of outcomes from aggressive behavior, locus of control, and school engagement, which have in fact been found to mediate treatment effects (Lochman & Wells, 2002; Leve & Chamberlain, 2007). Furthermore, few published studies have examined common factors (i.e., hypothesized change mechanisms shared by different psychotherapies,

for different disorders, such as therapeutic alliance, hope, and readiness for change) as mediators in RCTs of youth EBPs. The therapeutic alliance, despite having been documented as a significant predictor of outcome in a meta-analysis of 38 studies of youth psychotherapy (McLeod, 2011), has, to our knowledge, been subjected to a mediation test in only a single study (Kaufman *et al.*, 2005). Moreover, we are not aware of any published mediation studies for several EBPs (e.g., EIBI, IPT-A, FFT), which each have theoretical change models that could be empirically tested in mediation studies.

Fifth, at least two major multisite trials have found that combination treatment involving medication plus EBP was superior to medication alone and EBP alone—suggesting a need to study mediators and change mechanisms of combination treatments. As mentioned earlier, methylphenidate plus behavioral therapy was the most efficacious treatment in the MTA (MTA Cooperative Group, 1999); in addition fluoxetine (Prozac) plus CBT was the most efficacious treatment in the Treatment for Adolescents with Depression Study (TADS; TADS Team, 2004). Soberingly, in both these trials, combination treatment and medication alone, but not EBP alone, outperformed the control group (community care and pill placebo, respectively). In the MTA, both combination treatment and behavioral treatment alone improved parent discipline, but only for combination treatment was improved parent discipline related to improved child social skills and disruptive behavior (Hinshaw *et al.*, 2000). In TADS, both combination treatment and CBT alone increased adolescents' readiness to change (specifically, their action orientation), and increases in readiness to change were associated with reductions in depressive symptoms (Lewis *et al.*, 2009). However, pairwise contrasts of TADS treatment conditions were not conducted; thus, it is unclear if the mediation effect reported by Lewis and colleagues applies to both combination treatment and CBT. The bottom line is that we simply do not know exactly how medication and EBP combine synergistically to bring about superior effects; we need to uncover the mediators and change mechanisms targeted by combination treatments.

Moderators of evidence-based psychotherapies

Here, we review three categories of moderators—youth, caregiver, and methodological variables—found to be significant in meta-analyses of youth psychotherapies (encompassing multiple treatments, not exclusively EBPs) or in selected RCTs of youth EBPs.

Youth characteristics

Youth symptom severity, comorbidity, demographics, and other pretreatment characteristics are often tested as potential moderators of EBPs. The specific youth variables that emerge as significant moderators have varied across EBP and disorder. We exclude here a number of youth characteristics for which evidence is extremely mixed (e.g., age and gender), but we offer two examples of factors for which findings have been intriguing.

Pretreatment symptom severity was identified as a significant moderator in several meta-analyses and RCTs. Higher severity was associated with larger treatment effects in two meta-analyses—one of psychotherapy for youth depression (Watanabe *et al.*, 2007), the other of behavioral parent training for youth disruptive behavior (Lundahl *et al.*, 2006)—possibly because there is more room for improvement among severely symptomatic youths. However, higher severity has also been linked to *smaller* effects of combination treatment and medication alone in the MTA (Hinshaw, 2007). In addition, several RCTs have demonstrated that more symptomatic youths—unlike less symptomatic youths—derive greater benefit from more comprehensive, more intense, or family-focused therapies, compared to less comprehensive, less intense, or individual-focused therapies. For example, youths with more severe substance use and comorbidity at pretreatment benefited more from MDFT, which targets more risk factors including family interactions, than individual CBT or enhanced treatment as usual (Henderson *et al.*, 2010). Moreover, among adolescents with anorexia nervosa, those with more severe overall symptoms or eating/weight-related obsessions and compulsions benefited more from a year-long course of family therapy compared to adolescent focused therapy of the same duration (Le Grange *et al.*, 2012), and compared to a shorter 6-month course of family therapy (Lock *et al.*, 2005).

Comorbid diagnoses have moderated treatment effects among children with ADHD; for example, the subgroup with comorbid anxiety but no CD/ODD (conduct disorder/oppositional defiant disorder) responded equally well to behavioral treatment alone and medication alone, pointing toward behavior treatment as a potential first-line treatment for this subgroup of youths (Jensen *et al.*, 2001; Hinshaw, 2007).

Caregiver and family characteristics

Caregiver psychopathology, expressed emotion, and family demographics have been documented as significant moderators of EBPs. Here too, there is considerable variation across EBP and disorder in terms of which specific caregiver and family variables are treatment moderators, so again we offer just two examples of interesting findings.

Critical, hostile, and emotionally overinvolved attitudes toward the patient by close family members—termed expressed emotion (EE; Hooley & Parker, 2006)—moderated family therapy outcomes for adolescent anorexia nervosa in one RCT but not in another. High EE was associated with better response to separated family therapy than to conjoint family therapy (Eisler *et al.*, 2007). However, EE did not moderate outcome in another RCT comparing family therapy to adolescent focused therapy (Le Grange *et al.*, 2012). The authors surmised that separated family therapy may be especially suitable for adolescents from high EE families as it aims to reduce parent criticism while avoiding parent criticism during treatment sessions themselves. On the other hand, adolescent focused therapy aims to increase

adolescent autonomy and does not thoroughly address the high levels of parent criticism in high EE families.

RCTs of several EBPs have documented family structure and socioeconomic status (SES) as moderators. Meta-analyses of behavioral parent training for disruptive behavior (Lundahl *et al.*, 2006) and of behavioral and cognitive-behavioral interventions for ADHD (Corcoran & Dattalo, 2006) documented smaller treatment gains for youths from nonintact families; the first meta-analysis also documented smaller gains for low SES families. A plausible explanation is that single and low SES parents have less time and energy to attend therapy sessions and practice the skills learned during therapy in order to implement them effectively at home. Fortunately, there is also evidence that nonintact or low SES families benefit more from some versions of EBPs. Lundahl and colleagues' meta-analysis found that low SES families gained more from individual than group parent training, perhaps because the individual format allows greater attention to fitting the treatment to individual families' needs. In addition, adolescents with anorexia nervosa from nonintact families responded better to a year-long course than a 6-month course of family therapy (Lock *et al.*, 2005), suggesting that adolescents from nonintact families may need longer treatment to derive meaningful benefit. These findings could potentially guide treatment decisions for youths based on their family demographics.

Method factors

The previous sections have focused on sample characteristics; we turn now to methodological factors that may moderate treatment outcome.

One of these involves the fact that different informants can differ markedly in their perspectives on the same youth's behavior, and on the outcome of treatment. Youth psychotherapy studies usually include outcome and process measures from multiple informants; these may include the youths themselves, caregivers, therapists, assessors not involved in providing treatment, siblings, peers, and teachers. Informant discrepancies are common and may be due to informant differences in both perspective and opportunities to observe the youth (De Los Reyes & Kazdin, 2005). Understandably, the presence, magnitude, and even *direction* of treatment effects can depend on the particular outcome measure used, and which informant completes that measure. Treatment effects were larger for youth-report than for parent-report measures in a meta-analysis of youth depression psychotherapy RCTs (Weisz *et al.*, 2006b). Perhaps depressive symptoms such as sad mood are most salient to the youths experiencing them, and less so for outside observers, such that youths would be more sensitive to changes in their depressive symptoms than their parents would be. In a multisite trial of treatments for social phobia among children, parent-youth disagreement on youth symptoms at pretreatment were significantly associated with disagreement at posttreatment only among nonresponders to treatment (De Los Reyes *et al.*, 2010).

Another aspect of informant report that may moderate treatment outcome is whether the informants are blind to treatment assignment. One relevant finding emerged from a recent meta-analysis of 52 RCTs comparing youth EBPs for an array of internalizing and externalizing disorders to usual clinical care (Weisz *et al.*, 2013b): the benefit of EBPs over usual care was significant only for youth-report and parent-report measures (i.e., reports by those who had sought treatment and knew what the treatment was). Another recent meta-analysis obtained significant effects of behavioral treatments for ADHD that did not hold up when analyses were limited to outcome measures for which informants were likely to be blind to treatment condition (Sonuga-Barke *et al.*, 2013; but note also that significant effects of *dietary* interventions for ADHD were evident with both blind and unblinded informants). Several explanations may account for better outcomes reported by unblinded informants: (a) informants who know about the treatment may be more invested in perceiving it as successful; (b) unblinded informants (e.g., youths and their caregivers) tend to also be those who have the most accurate and complete information about youth functioning; or (c) the measures most often taken via blinded informants are lacking in validity (e.g., observational ratings may not adequately sample the youth's behavior, or youths may behave in atypical ways when being observed).

A third method factor warranting attention is the setting in which treatment takes place and in which youth behavior and outcomes are assessed. Numerous reviews (e.g., Weisz, 2004) have noted that distinctive settings can carry distinctive constraints and can facilitate and inhibit very different behavior. The same youth may be very well regulated within a highly structured residential program but quite dysregulated at home or in school when the potent structure is no longer present. An effective behavioral parent training intervention may produce marked improvements in youth behavior at home that do not generalize to behavior in school. Prompted in part by such findings, the 2013 National Institute for Health and Care Excellence (NICE) guidelines for treatment of youth conduct problems in the UK recommend a multimodal approach (see Scott *et al.*, 2013, p. 33) in which treatment within the family is complemented by treatment focused on the school and other settings where youth behavior may be at issue. The challenge of cross-setting differences and the closely linked challenge of effect generalization warrant careful research attention in the days ahead.

Therapist adherence and competence

We end this section on a puzzling note: findings across multiple studies have been quite mixed in regard to whether higher levels of therapist adherence to treatment manuals, and higher levels of measured therapist competence in the component skills, are actually associated with better or worse treatment outcomes, or no difference (see, e.g., Hogue *et al.*, 2008; Webb *et al.*, 2010; Weisz *et al.*, 2012). Until there are more convergent findings (and perhaps refined measurement strategies will help), this

important topic may remain shrouded in uncertainty, awaiting an empirical breakthrough.

Adapting and testing psychotherapies for diverse populations

In recent years, investigators have begun to examine the potency and reach of youth EBPs by evaluating their impact across a more and more diverse array of at-risk populations. We illustrate by focusing on four populations of special interest.

Ethnic minority populations

The massive movement of population groups across national boundaries—due to violent conflict, repression, and pursuit of educational and employment opportunity—has created ever-higher percentages of “minority youths” in countries around the world. In the United States, for example, 2008 statistics showed that 43% of youths belonged to ethnic minority groups, and that percentage has continued to increase (Mather & Pollard, 2009). About 13% of minority youths receive mental health services in the United States each year (Stagman & Cooper, 2010), but some reports on treatment process and outcome have not been encouraging. For example, a US Department of Health and Human Services report (DHHS, 2001) showed that only a small number of ethnic minorities had participated in psychotherapy RCTs, and these studies did not assess the efficacy of the treatment by ethnic status. In addition, some research found that ethnic minority youths were significantly more likely than European-Americans to drop out of treatment (Kazdin & Whitley, 2003), and less likely to show significant clinical improvement when treated for depression (Weersing & Weisz, 2002a).

The results of a selective review conducted by Huey and Polo (2008) of youth treatment outcome studies from 1960 to 2006 were more promising. At least 75% of participants in each study were ethnic minorities. Using the levels-of-support criteria described earlier (see Silverman & Hinshaw, 2008), Huey and Polo found no “well-established” treatments for ethnic minority youths, but they identified a number of “probably efficacious” and “possibly efficacious” treatments for a range of psychological disorders including anxiety, ADHD, depression, conduct problems, substance use, posttraumatic stress, and suicide risk, with CBT as the best-documented EBP for anxiety disorders, depression, and trauma-related disorders. Adding a meta-analysis of 25 studies, Huey and Polo found a mean pre–posttreatment effect size for ethnic minority youths averaging 0.44, just below a medium effect (Cohen, 1988).

Lower and middle-income countries and war-exposed youths

Limited research on mental health has been conducted in lower- and middle-income countries (LAMICs); this constitutes 3–6% of published mental health research (Saxena *et al.*, 2006). This

research gap is attributed to a range of factors, including limited mental health resources, a lack of trained mental health professionals, and child mortality concerns taking priority over morbidity (Patel *et al.*, 2008).

Mental health efforts in LAMICs have primarily focused on the youths most in need of support: youths exposed to armed conflict in war-torn regions (see Chapters 16 and 44). These youths have experienced extreme psychosocial stressors such as military assault, sexual trauma, conscription as “child soldiers,” and various consequences associated with involuntary displacement (e.g., refugee camps, a new and unfamiliar local language and culture, separation from family members). Thus, war-exposed youths are at heightened risk for substance use, depression, anxiety, conduct problems, posttraumatic stress, and suicidal ideation (Shaw, 2003; Lustig *et al.*, 2004).

The modest research conducted to date on treatment for war-exposed youths is somewhat encouraging. Bolton *et al.* (2007) assessed a group interpersonal therapy (IPT) intervention for depression among adolescent Ugandan war refugees. Compared to a creative play program and wait-list control, IPT was significantly more effective in reducing depression symptoms (but not anxiety or conduct problems) for girls; symptom reductions occurred for boys but were nonsignificant. Dybdahl (2001) assessed a psychosocial treatment focused on parent trauma-processing and improving mother–youth interactions for mother–youth refugee dyads internally displaced within Bosnia. The treatment group showed significantly greater improvement in mothers’ PTSD symptoms and youths’ psychosocial functioning (youths’ PTSD symptoms were not explicitly assessed), as compared to a control group.

Large-scale RCTs have also been conducted as school-based interventions. Trauma and grief component therapy (TGCT) has been widely disseminated in Bosnia as part of a UNICEF mental health program. Layne *et al.* (2008) assessed the effectiveness of school-based TGCT for Bosnian adolescents with PTSD, depression, or grief symptoms. Students participated in one of two treatment conditions consisting of components of TGCT: trauma- and grief-centered therapy with psychoeducation and social skills training (treatment condition), or psychoeducation with social skills training (active comparison group). Both TGCT groups showed a significant reduction in PTSD and depression symptoms, but only the treatment condition showed a significant reduction in grief symptoms. Jordans *et al.* (2010) assessed a classroom-based intervention in civil-war-affected Nepal designed to improve general well-being and psychosocial functioning among adolescents. The intervention consisted of CBT, narrative exposure techniques, and structured play. Compared to a wait-list control, the treatment group experienced significantly greater improvements in overall functioning, general psychological functioning, and greater reduction in depression and anxiety symptoms. PTSD symptoms decreased and feelings of hope increased to a similarly significant degree in both groups. Tol *et al.* (2008) tested a similar CBT intervention for PTSD symptoms among youths in

Indonesia exposed to political violence, and the treatment group showed a significantly greater reduction in PTSD symptoms (but not depression or anxiety symptoms) compared to a wait-list control. These studies show promising initial dissemination efforts of evidence-based treatments to war-exposed youths even in remote and limited-resource regions. Perhaps these early findings will be a springboard for work with other LAMIC populations greatly in need of support.

Youth offenders in the juvenile and criminal justice system

Previous studies have found a high prevalence of psychological disorders in incarcerated youth offenders. Teplin and colleagues (2006) found that the most common disorders included conduct-related, substance use, and affective disorders, with comorbidity quite substantial. The primary objective of the juvenile justice system is rehabilitation, and treatment for mental health problems is widely viewed as essential. However, there is little empirical support for many of the interventions used, and some may be ineffective or harmful. Lipsey and Wilson (1998) conducted a meta-analysis of 200 intervention studies for juvenile offenders and found a small effect for reduction in rate of reoffending (average effect size of 0.1).

The Blueprints for Violence Prevention project of the Center for the Study and Prevention of Violence, at the University of Colorado, has evaluated over 900 programs designed to rehabilitate juvenile delinquents (Mihalic *et al.*, 2002). Evidence in support of most of these programs (e.g., boot camp, summer job programs) was found to be either disappointing or entirely lacking. Arguably the strongest evidence supports Multisystemic Therapy (MST; Glisson *et al.*, 2010; Henggeler & Schaeffer, 2010; Schoenwald, 2010), an intensive intervention targeting multiple systems in youths' lives, including family support and relationships, neighborhood and peer networks, and their teachers and school. Across multiple trials, MST has been shown to significantly reduce rate of reoffending, improve parenting skills and family relations, enhance positive social networks and prosocial activities, and improve grades and vocational skills. MST has been shown to be more effective than common "usual care" alternatives, including probation services, child-welfare systems, and individual outpatient therapy (Weisz *et al.*, 2013b). Unfortunately, practices found to be ineffective, or even harmful, continue to be widely used.

Youths cared for in child protection programs

Child protection and child welfare systems are typically designed to balance the value of family cohesion against the need to protect children from maltreatment. These systems may remove children from their home or assist parents in child rearing. The youths involved often have significant mental health needs, sometimes related to family stress or maltreatment they experienced, sometimes to the process of foster placement (often a series of placements), and sometimes to diverse factors not all of which can be identified. Unsurprisingly, admittance into the

child protection system is a common precursor to mental health services (see Garland *et al.*, 1996; Garland *et al.*, 2001a, b).

Successful interventions for these youngsters often engage multiple systems in the youths' lives. One example, Multisystemic Therapy for Child Abuse and Neglect (MST-CAN), consists of the standard components of MST in addition to safety planning, parental anger management, and family problem-solving and communication training. In one RCT, MST-CAN was shown to be more effective than enhanced outpatient treatment in reducing youth psychopathology symptoms and placement changes, and improving parent functioning, including reduced maltreatment (Swenson *et al.*, 2010).

Another successful approach is Multidimensional Treatment Foster Care (MTFC; Smith & Chamberlain, 2010). MTFC involves working with youths, biological parents, and foster parents using a multilevel intervention implemented in family, community, and school settings. Each youth is placed in a foster home for 6–9 months, where an intensive individualized behavior management program is implemented. Parents attend family therapy, and learn parenting strategies including limit-setting and positive reinforcement of prosocial behaviors. MTFC has been shown to be more effective in reducing youth delinquent behavior than standard group care (Chamberlain & Reid, 1998; Chamberlain *et al.*, 2007). Other MTFC trials have found reductions in severe youth mental health problems (Chamberlain *et al.*, 1992).

Youths in the child welfare system with histories of maltreatment who are at increased risk for PTSD may need trauma-focused mental health services. The most thoroughly tested of these is Trauma-Focused Cognitive Behavioral Therapy (TF-CBT; Cohen *et al.*, 2010). TF-CBT integrates traditional CBT with trauma-specific methods, including narrative exposure therapy, safety planning, and graduated exposure to trauma-related cues. RCTs have shown TF-CBT to be more effective in reducing PTSD symptoms than wait-list control, "supportive therapy," and "child-centered therapy" (see review in Cohen *et al.*, 2010).

Putting science into practice: EBPs and the clinical practice of youth mental health care

A central goal for so many who develop treatments and conduct treatment outcome research is to improve mental health care for the many girls and boys who struggle with problems and disorders in their everyday lives. Because most of these youngsters will never participate in a treatment trial, prospects for them to benefit from the research will depend on the extent to which that research informs and improves everyday clinical practice. This means that the interventions developed and tested will need to be appropriate for and adopted by clinical practice, and when used in practice will actually lead to improved outcomes. We now take stock of how well youth treatment research is doing in relation to these objectives.

Dissemination and implementation of evidence-based practices

The objectives are closely related to the subfield now known as dissemination and implementation science. Dissemination has been defined (National Institute of Mental Health [NIMH] 2009) as:

...the targeted distribution of information and intervention materials to a specific public health or clinical practice audience. The intent is to spread knowledge and the associated evidence-based interventions.

Implementation has been defined (NIMH, 2009) as:

the use of strategies to adopt and integrate evidence-based health interventions and change practice patterns within specific settings.

What grade should we give youth psychotherapy research on the complementary tasks of dissemination and implementation? On the one hand, there is now extensive publicity for EBPs, within prominent journals and through government entities in many nations. On the other hand, despite all the publicity, most of the tested treatments are still used mainly in treatment trials; most have not made significant inroads into everyday clinical care. Studies in North America show very low levels of EBP use in everyday practice (see Weisz *et al.*, 2009; Brookman-Frazee *et al.*, 2010; Garland *et al.*, 2010; Southam-Gerow *et al.*, 2010). Complementing these reports, a UK survey published in 2006 by the Association for Child and Adolescent Mental Health (see http://www.acamh.org.uk/POOLED/articles/bf_eventart/view.asp?Q=bf_eventart_213513) found that CBT was the dominant approach of only 20% of practitioner respondents, despite very substantial government pressure favoring CBT (e.g., via the NICE guidelines). While the data from North America and the United Kingdom certainly do not cover all practice or training sites, they do suggest that EBPs are not making their way into training or practice very quickly. Why not? Why wouldn't professionals who chose careers to help young people be eager to adopt practices that have been tested and shown to work?

Goodness-of-fit issues in the design of evidence-based practices

One answer may relate to the design of the tested practices. Research in clinical care settings and with practitioner partners (e.g., Weisz, 2004; Weisz *et al.*, 2005b, 2013a) has raised significant design concerns. One is the fact that most of the EBPs (see Table 36.1) are designed for single problems or disorders (or homogeneous clusters—e.g., a few depressive disorders). For practitioners, whose caseloads tend to be broad and heterogeneous, with an array of disorders and significant comorbidity within cases, learning one or two single-disorder EBPs may not be seen as useful enough to warrant the time and cost. An additional concern is that EBPs tend to ask a lot of therapists—learning a detailed manual, much more advance preparation for each session than may seem feasible in everyday

practice, working from an agenda rather than letting the session flow freely, and devising ways to make the manualized content engaging and motivating for the youth. None of these challenges is insurmountable, but each may require attention in efforts to disseminate EBPs, and even in the very development and testing of EBPs, a topic to which we turn next.

Context of EBP development and testing versus conditions of everyday practice

The structure and content of EBPs, and the degree to which they fit the conditions of everyday practice, may have a lot to do with the conditions under which they are created and tested. In general, these conditions have differed markedly from the conditions of actual clinical practice (Weisz *et al.*, 2005a; Weisz & Gray, 2008). This difference may impose certain limits on prospects for extrapolating from research findings to treatment in youth clinical service settings. The difference may also have slowed the pace of dissemination and implementation, to some degree, in part by raising practitioner concern over whether these treatments that look promising in research are actually appropriate for their use in real-world clinical practice.

The research versus clinical practice differences surface in multiple areas, including therapy participants, treatment settings, and even the broader policy and fiscal context. Youths treated in clinical practice settings may differ from those recruited for RCTs in diverse ways, including severity and family adversity (Hammen *et al.*, 1999; Southam-Gerow *et al.*, 2003). Clinicians employed in clinics differ from research-employee therapists in background and training, daily working conditions, incentive structure, and professional goals (see Weisz & Addis, 2006; Palinkas *et al.*, 2008). In addition, clinical practice and research organizations differ in multiple ways relevant to implementation of EBPs; for example, in practice settings, time, productivity, financial, and other work pressures can make it hard to allocate time to the training and ongoing case consultation needed for successful implementation of EBPs (Weisz & Addis, 2006). Such differences—encompassing the patients, therapists, and settings of therapy—illustrate the stark gap between the world of clinical research and that of clinical practice.

(Un)Representativeness of most research on evidence-based youth psychotherapies

In principle, that gap might be addressed by conducting much of the research that leads to EBPs in representative clinical practice contexts. In fact, though, such research has been rare, to date. The problem is illustrated by Table 36.2, which summarizes relevant details of 461 youth psychotherapy RCTs from the 1960s to 2009. As shown in the table, the large majority of trials used (a) recruited (not clinically referred) samples, (b) therapists who were research employees (not practicing clinicians), and (c) university lab or other nonpractice settings. The table also shows that representativeness has increased somewhat in recent decades, but only 2.1% of all the studies, and only 4.5% of studies in the most recent decade, focused on clinically referred clients,

treated by practitioners, in clinical practice settings (see also Weisz *et al.*, 2005a, for a similar analysis and similar conclusions). What seems clear is that most of the research that leads to the establishment of EBPs has been carried out in contexts quite different from the world of clinical practice for which the EBPs are ultimately intended. One result may be a collection of treatments that are a less than perfect fit to that clinical practice world.

Do EBPs actually produce better outcomes than usual clinical care?

Concerns about the fit between EBPs and usual clinical practice lead quite naturally to a critical question: Do EBPs produce better outcomes than the treatments youths would otherwise receive through usual clinical care? In some respects, this is the most basic question many in clinical practice might ask. Given the very substantial funding and time required to build competence in a typical manual-guided EBP, it is reasonable for practitioners, clinic directors, policy makers, and funders to ask whether shifting from usual treatment practices to EBPs will, in fact, lead to better youth outcomes than current practices do. Youth treatment research has not emphasized the kinds of studies that could answer that question—that is, RCTs in which youths with significant mental health problems or disorders are randomly assigned to a specific EBP or to usual clinical care. However, a limited pool of such studies does exist, and we turn to those studies next.

Our search for relevant studies has led to two meta-analyses focused on methodologically acceptable studies that have directly compared usual care to youth psychotherapies that have been formally classified as EBPs. In these two meta-analyses (32 studies in Weisz *et al.*, 2006b; 52 studies in Weisz *et al.*, 2013b) studies spanned the years 1973–2010, and youth ages ranged from 3 to 18 years. Most of the EBPs were specific behavioral or CBT interventions, and about a fourth were systems-oriented approaches such as MST. On average, the EBPs did outperform usual care. However, the mean posttreatment effect size was only 0.30 and 0.29, in the first and second meta-analysis, respectively, falling between conventional cutoffs for “small” and “medium,” and markedly lower than mean effects found in prior meta-analyses (see Figure 36.1). To put the findings into context, a mean effect size of 0.29–0.30 translates into a probability of only 58% that a randomly selected youth receiving an EBP would be better off after treatment than a randomly selected youth receiving usual care. Also worrisome: in the 2013 meta-analysis, there was no significant advantage of the EBPs with two key subgroups: clinically referred samples and youths in samples severe enough to be clinically diagnosed. A more pessimistic picture was presented in Spielmans and colleagues’ (2010) reanalysis of the Weisz *et al.* (2006b) meta-analysis. These authors controlled for factors they believed might bias study findings in favor of EBPs, and concluded that EBPs did not significantly outperform usual care. Readers might also find some support in both the Spielmans *et al.* and Weisz *et al.*

meta-analyses for the notion that effect sizes shrink when EBPs are tested by independent investigators with no involvement by the program developers (see Eisner, 2009). One conclusion on which all the meta-analysts would likely agree is that outcomes have been highly variable across studies, with a number of studies showing usual care outcomes to be similar or superior to EBPs outcomes. This variability is shown in Figure 36.2, for the Weisz *et al.* (2013b) meta-analysis study sample.

Strategies for strengthening youth psychotherapies and intervention science

The findings reviewed thus far point to a lively field with committed researchers actively searching for beneficial youth treatments. The findings also suggest strategies for building stronger treatments and improving the evidence base on youth psychotherapy.

Making intervention research look more like practice

A significant limitation of the evidence base, shown in Table 36.2, is that intervention research shows relatively low relevance to actual clinical practice. We have argued (e.g., Weisz, 2004; Weisz & Gray, 2008) for a *deployment-focused model* within which interventions are developed and tested, as soon as feasible, with the kinds of therapists and clients, and in the kinds of settings, for which the interventions are ultimately intended. If this model were adopted, the form of research known as efficacy testing (e.g., with recruited samples treated by research-employee therapists under experimenter-designed conditions) would be only a brief initial phase in intervention development, used to establish potential for benefit, and effectiveness testing under clinically representative conditions would be the dominant research approach. This in turn would provide a more direct path than now exists between research on youth psychotherapy and effective applications of the products of that research within everyday youth clinical care.

Tapping the heuristic potential of usual care

Speaking of usual care, our evidence suggests that it may have something to teach us. Figure 36.2 revealed that some forms of usual care produced outcomes comparable to or better than the outcomes of EBPs, suggesting that some treatments arising from everyday practice may deserve to be documented in written protocols and tested in their own right. For this to be feasible, however, investigators will need to stop treating usual care as a mere “control condition” and think of it instead as a source of ideas and methods. Weisz *et al.* (2006a) noted that the studies in their meta-analysis generally provided excellent documentation of EBP content but very poor documentation of the usual care conditions to which the EBPs were compared, leaving it unclear what “usual care” actually consisted of. This problem needs to be solved if we are to maximize the hypothesis-generating potential

Table 36.2 Percentage of groups in youth psychotherapy outcome studies that employed clinically representative youths, therapists, and treatment settings.

Decade	1960s	1970s	1980s	1990s	2000s	All decades
Number of studies	13	62	99	100	187	461
Number of groups	35	183	273	244	425	1160
How youths were enrolled in study						
Recruited, nontreatment-seeking	62.9	85.8	65.9	57.8	62.8	66.1
Clinic-referred, treatment-seeking	5.7	4.9	24.2	26.2	24.5	21.1
Required via court/justice system	17.1	8.2	8.8	11.5	7.8	9.1
Enrollment method not reported	14.3	1.1	1.1	4.5	4.9	3.6
Who provided the treatment						
≤50% therapists are practitioners	65.7	42.1	55.3	40.2	35.5	43.1
>50% therapists are practitioners	2.9	9.8	7.7	10.7	19.1	12.7
Therapist vocation not reported	14.3	27.9	23.4	32.0	25.4	26.4
No treatment/wait-list	17.1	20.2	13.6	17.2	20.0	17.8
Where treatment took place						
Research setting	11.4	6.6	9.9	18.4	19.5	14.7
Custodial, school, supervised setting	8.6	29.5	32.6	20.5	22.6	25.2
Clinical service setting	0	2.7	5.9	11.5	14.8	9.7
Correctional setting	14.3	1.1	5.1	4.1	2.1	3.4
Treatment setting not reported	48.6	39.9	33.0	28.3	20.9	29.1
No treatment/wait-list	17.1	20.2	13.6	17.2	20.0	17.8
Number of representativeness factors						
No factors reported	91.4	83.6	70.0	63.9	61.2	68.3
One factor reported	8.6	15.3	22.7	25.4	23.8	22.1
Two factors reported	0	1.1	7.0	9.0	10.6	7.6
Three factors reported	0	0	0.4	1.6	4.5	2.1

Note: Because treatment provider and setting are group-level variables, percentages of groups rather than percentages of studies are reported for all three variables. Three studies that employed a combination of nontreatment seeking and treatment seeking youths, and one study with a treatment condition that employed a combination of clinical and research settings, were excluded from analyses.

of EBP versus usual care research. Methods are now available for documenting usual care contents through a standardized clinician checklist (Weersing *et al.* 2002) and through a system for observer coding of intervention sessions (McLeod & Weisz, 2005, 2010). The checklist has been used to describe usual care for a variety of youth problems and conditions (Weersing *et al.*, 2002), and the observational coding system has been used to document characteristics of usual care in treatment of youth disruptive disorders (Brookman-Frazee *et al.*, 2010; Garland *et al.*, 2010) and depressive and anxiety disorders (Weisz *et al.*, 2009; Southam-Gerow *et al.*, 2010). In the next generation of studies, these and related methods could be used to characterize those patterns of usual care that show evidence of benefit.

Taking risks and learning from both failure and harm

The need for more potent treatments argues for testing creative ideas and daring ventures—high-risk/high-gain efforts toward breakthrough innovations in treatment. However, taking risks with daring innovations virtually ensures some failures. Each

failure may add valuable information on treatments that *do not* work—an important complement to learning what *does* work; both form the empirical tapestry of our science. As any meta-analyst would note, reporting failures is critical to a balanced picture; woe be the science in which only positive results are published. Failure can also be a springboard for treatment refinement and improvement, as when group intervention with antisocial youths was found to produce iatrogenic “peer contagion” or “deviancy training” effects, suggesting the need for a different approach (Dishion & Dodge, 2005), or when the discovery that a particular implementation of parent training did not work suggested innovative enrichment strategies (Scott & Dadds, 2009). Evidence indicates that even evidence-based treatments can have harmful effects if poorly executed (Scott, 2013), thus highlighting the need for rigorous implementation. Treatment failure or weak effects can also prompt useful tests of dose-augmenting strategies, such as boosters and relapse prevention, in programs for both internalizing and externalizing problems (see e.g., Tolan *et al.*, 2009; Clarke & DeBar, 2010).

Figure 36.2 Effect sizes of individual studies comparing evidence-based youth psychotherapies (EBPs) to usual care. Horizontal bar at 0.29 shows mean effect size across the full study set. Bars below zero show studies in which usual care produced outcomes superior to those of EBPs. Note the number of studies for which usual care showed effects similar to or superior to EBPs. *Source:* Reprinted with permission from John R. Weisz.

Restructuring evidence-based psychotherapies to fit clinical practice needs

We suggested earlier that many EBPs are designed in ways that may not match up well with the clients, clinicians, and settings of everyday clinical care. For example, most EBPs are built for a single disorder or a small homogeneous cluster, whereas most clinicians carry diverse caseloads, such that one EBP for one disorder may fit only a tiny portion of their clientele. Single-disorder EBPs may also not mesh well with the fact that most referred clients have comorbid conditions, and that the most pressing problems that need attention can

shift during treatment, rendering the single focus with which treatment began to then be no longer so relevant. One approach to addressing the problems of diverse caseload, client comorbidity, and flux in treatment is to build integrative treatments that combine intervention components from multiple EBP, encompassing multiple different problems and disorders. As an example, Chorpita and Weisz (2009) developed a *modular* protocol for child and adolescent disorders and problems involving anxiety, depression, and disruptive conduct. In a recent randomized effectiveness trial, this protocol produced significantly better clinical outcomes than (a) usual outpatient care and

(b) standard single-disorder protocols (Weisz *et al.*, 2012). Such integrative treatments may not only improve effectiveness but boost efficiency, reducing the need to do multiple trainings and to navigate multiple single-disorder protocols.

Improving care through monitoring and feedback

Another development that may improve clinical care and outcomes is the design and regular use of information systems that provide feedback on client response. Such a system was used with the modular protocol for youth, described in the previous paragraph (Chorpita & Weisz, 2009); the system provided weekly feedback on youth progress throughout treatment using two brief, psychometrically sound measures (Chorpita *et al.*, 2010; Weisz *et al.*, 2011), displayed on a “client dashboard” within an accessible web-based system. Recent research indicates that providing such client progress feedback to clinicians, even in the absence of EBPs, may improve therapy success and reduce deterioration among adults (Lambert *et al.*, 2002; Anker *et al.*, 2009) and improve therapeutic relationships and outcomes among youths (Stein *et al.*, 2010; Bickman *et al.*, 2011).

Enriching our understanding of what makes treatments work

Although we listed 40 youth EBPs at the beginning of this chapter, we have found very few replicated mediators of youth EBPs, and there is literally no evidence on whether any of these actually preceded changes in outcome. In fact, reviews (Weersing & Weisz, 2002b; Chu & Harrison, 2007) indicate that potential mediators of youth EBPs are often measured but not subjected to formal mediation testing. Consequently, we know a lot about *which* psychotherapies work for youth, but we know remarkably little about *how* these treatments work. This is unfortunate because understanding change mechanisms can help us build potent models of behavior change that can, in turn, inform development of powerful treatments (Kazdin & Nock, 2003). Identifying true mechanisms of change is resource-intensive, requiring frequent measurement of multiple candidate mediators and outcomes as well as experimental manipulation of mediators (Kazdin, 2007). But the effort may well be warranted, especially as we now have particularly promising statistical methods (e.g., bias-corrected bootstrapping, joint significance testing, and PRODCLIN asymmetric confidence-intervals testing; see Fritz & MacKinnon, 2007) for drawing strong inferences about the active ingredients that make treatments work.

Building efficient and accessible delivery methods and models

To increase accessibility and cost-effectiveness of treatment, some researchers have deviated from traditional in-person talk therapy. In fact, Kazdin and Blase (2011) have proposed a “portfolio” of treatment delivery methods to increase the public health impact of psychotherapies. These methods may include

(but certainly not be limited to) self-help books that impart EBP-related skills (e.g., Forehand & Long, 2010), treatments enlivened through video materials (e.g., Webster-Stratton & Reid, 2010), therapies delivered by paraprofessionals (e.g., Yu & Seligman, 2002), and therapies embedded within everyday settings such as summer camps (e.g., Pelham *et al.*, 2010). Such approaches may increase the uptake and spread of EBPs by reducing cost, travel time, logistical barriers, and even the stigma associated with traditional treatment methods, and by boosting engagement for many.

Another approach noted by Kazdin and Blase (2011) deserves special attention: the use of computer and internet technology (see Enock & McNally, 2013, for a review and relevant model). As one example, Kendall and Khanna (2008) developed a computer-assisted treatment for youth anxiety disorders, Camp Cope-A-Lot, based on the Coping Cat program. The youngster interacts with animated figures on the monitor to complete session activities, and the therapist coaches the patient through the program. Merry and colleagues (2012) developed SPARX, a computer-based treatment for youth depression. SPARX is a video game that conveys CBT skills such as problem solving, cognitive restructuring, and relaxation. Initial evidence suggests that both Camp Cope-A-Lot (Kendall *et al.*, 2011) and SPARX (Merry *et al.*, 2012) may be as effective as standard individual CBT.

Technology-assisted interventions for conduct problems also appear promising. As one example, Enebrink and colleagues (2012) developed an Internet-based version of parent management training that includes illustrations and video clips illustrating positive parenting strategies; this Internet PMT significantly outperformed a wait-list control condition in reducing youth conduct problems, increasing youth prosocial behavior, and enhancing positive parenting. Thus, early evidence suggests that some efficient, low-cost technology-assisted approaches to treatment may be no less effective than costly traditional methods. With further advances in technology, expansion of these alternatives seems quite likely and potentially promising.

Ideally, efforts to improve efficiency and cost-effectiveness would be guided by precise methods of calculating the cost of each approach. However, the calculations for, say, implementing a traditional manualized EBP may include the expense of initial training, ongoing expert supervision, therapist time preparing for sessions, therapist billing time foregone (during trainings and supervision), clinic administrative time, and other factors for many of which precise costs may be difficult to nail down. This may make it difficult to nail down the benchmark cost of standard approaches, and thus how much costs have been reduced by the use of technology and the other innovations noted in this section. Future collaboration with our health care economist colleagues could sharpen our ability to calculate costs precisely and thus assess whether, and if so how much, cost-effectiveness is boosted by these new approaches.

Summary and concluding comment

Research on youth psychotherapy has achieved remarkable gains in only five decades. There is now a rich treasury of tested treatments for an array of youth problems and disorders, an evolving process for evaluating the strength of the evidence for each of these, a vibrant intervention science focused on understanding how these treatments work and under what conditions, and a groundswell of interest and enterprise focused on strategies for making these treatments more and more accessible to more and more youths and families. There is a great deal of room for improvement in the interventions themselves and in the science that guides their development and refinement. Nonetheless, 50 years of research have produced a remarkable body of work and a remarkable launch for the scientific study of youth psychotherapy.

³Centre for Evidence-Based Intervention, Department of Social Policy and Intervention, University of Oxford, UK

Introduction

A parenting program is a specific intervention designed to improve the overall quality of parenting that a child receives. Parenting programs aim to help the way mothers and fathers relate to their child: primarily by changing their behavior in moment-to-moment interchanges throughout the day, although they also address parental beliefs and feelings. Change is achieved through the training of specific skills such as collaborative play, selective attention and praise to promote sociable behavior, and clear rules backed by consistently applied consequences to reduce misbehavior. There is a structured sequence of sessions that build up each of the competencies. This approach to intervention, in which the emphasis is usually on understanding the parents' views and giving them nondirective general support, but not coaching them, is distinct from counseling (see Chapter 40); it differs from psycho-education in which a parent is informed about the nature of the child's disorder and given advice on management but not trained. In family therapy, the therapist typically addresses the whole family system, often with a primary emphasis on a deeper understanding of interpersonal processes and meanings; it is the change in understanding, rather than skills, that should lead to changes in relationships (see Chapter 39).

Parenting programs often aim to improve child symptoms as well as improving the quality of the relationship, but this is not inevitable. Thus where neglectful or abusive parenting has been uncovered, the goal may be to improve positive parental engagement with the child and reduce harsh emotional and physical practices, whether or not the child is displaying problems (see Chapter 29). Moreover, where there are child-specific emotional or behavioral problems, parenting programs may help, whether or not suboptimal parenting has contributed to causing the problem. Thus programs can help parents to better manage children with problems that are mainly genetically influenced, such as autistic spectrum disorders (see Chapter 51) or children

with obsessive-compulsive disorder (see Chapter 61) although parenting quality is satisfactory at the outset.

Furthermore, where there are child symptoms and parenting is less than optimal, this does not necessarily mean that the parenting caused the child's problems. Parent-child relationships are bidirectional and more difficult child behavior can elicit harsher parenting. Several lines of evidence show this, from the classic experiment in which parents with relatively well-behaved children were asked to look after children with behavioral problems and became harsher and more critical (Anderson *et al.*, 1986), to experiments showing that where disruptive child behavior such as ADHD is reduced by medication, parenting quality improves (Schachar *et al.*, 1987). Two areas of child functioning where parenting has been strongly implicated as causing difficulties are conduct problems and insecure attachment; we concentrate on these domains in this chapter, but refer to others.

Styles of parenting addressed by parenting programs

As there are many different theories of what constitutes good parenting, there are many different approaches incorporated in intervention programs. We focus here on those dimensions that are well empirically supported and that have led to proven intervention programs.

Dimensions of parenting addressed in interventions derived from social learning theory

Social learning theory evolved from general learning theory and behaviorism (Bandura, 1977). The notion is that children's real-life experiences and exposures directly or indirectly shape behavior; processes underlying this learning can be diverse. In interventions, there has historically been a near-exclusive focus on externally observable behavior rather than children's inner mental states (Patterson, 1982). Operant behavioral principles of reinforcement and (noncoercive) consequences are applied immediately after the child has acted/responded; there is less

emphasis on classical, stimulus-controlled conditioning (Scott, 2008). Moment-to-moment exchanges are crucial: if a child receives an immediate reward for their behavior, such as getting parental attention or approval, then they are more likely to repeat the behavior, whereas if they are ignored or an unwelcome sanction is applied, then they are less likely to do it again.

Patterson (1982) showed how children's aggressive behaviors were learned from and reinforced by parallel negative behaviors by parents. A negative parenting style appears to have a causal role in leading to conduct problems, even after allowing for child effects. The association has been repeatedly found in (i) large-scale epidemiological investigations, such as those in New Zealand and UK (e.g., Isle of Wight); (ii) intensive clinical investigations such as Patterson's work mentioned earlier; and (iii) numerous naturalistic studies of diverse samples using a mixture of methods (e.g., Gardner *et al.*, 1999; Denham *et al.*, 2000). The parenting behaviors identified are high criticism and hostility, harsh punishment, inconsistent discipline, low warmth, involvement and encouragement, and poor supervision.

A further important dimension is supervision of child activity, and monitoring their whereabouts and activities outside the home. Careful monitoring has greater effects in neighborhoods where there are many risks such as drugs and violence (Pettit *et al.*, 1999). Monitoring is not just a matter of parents being good "policemen", as knowing the whereabouts of a child depends in part on the child having a good enough relationship to tell the parent what they are doing (Racz & McMahon, 2011). Therefore, enabling parents to impose effective discipline depends on their also developing a positive relationship, skills addressed in most modern programs. These elements promote child positive behavior and affect and provide a more positive relationship context for parental disciplinary interventions. They improve child behavior (Gardner, 1987) and attachment (Scott *et al.*, 2011).

More recently, social learning models have increasingly considered inner cognitive or "mindful" processes, such as attributions and expectations that underlie parents' behavior (Snarr *et al.*, 2009). More negative attributions about a child predict poorer child outcomes over and above observed parental behavior (Doolan, 2006), and addressing them in interventions leads to better child outcomes (Sanders *et al.*, 2004). Beliefs can vary considerably across cultures, with more traditional societies showing more authoritarian views, particularly among fathers. Parenting programs based on "Western" values need to address different cultural beliefs regarding how best to bring up a child, but if they do this, they can be equally effective in improving parenting in ethnic minority groups (Reid *et al.*, 2001; Scott *et al.*, 2010a).

Dimensions of parenting addressed in interventions derived from attachment theory

Attachment theory (Bowlby, 1969/1982; see Chapter 6) focuses on the extent to which the relationship provides the child with protection against harm and a sense of emotional security,

resulting in a "secure base" for exploration. The theory proposes that the quality of parental care, particularly sensitivity and responsiveness to the child's emotional needs ("sensitive responding"), promotes a relationship characterized by warm, expressive to-and-fro interchanges ("mutuality"), leading to secure attachment. Evidence shows that sensitive responding is important in promoting attachment security, but less than theorized (De Wolff & van IJzendoorn, 1997; see Chapter 6). Longitudinal studies confirm that attachment security does not shape subsequent development deterministically, but interacts with child and family factors to influence outcome (Sroufe *et al.*, 2010). A particularly harmful parenting style is frightening and abusive parenting, which is associated with "disorganised" attachment patterns—meta-analyses confirm a strong association with maltreatment (Cyr *et al.*, 2010). Disorganization is associated with many forms of child psychopathology, especially conduct problems (Fearon *et al.*, 2010), although it is important to note that it occurs in 15% or more of normal populations.

Over time, attachment relationships are internalized and carried forward to influence expectations for other important relationships, by an "internal working model." In the last decade, progress has been made in measuring internal working models, in childhood using doll-play story-stems (Green *et al.*, 2007) and in adolescence using semi-structured interviews (Shmueli-Goetz *et al.*, 2008). These measures have shown that attachment insecurity continues to be associated with higher levels of psychopathology in middle childhood (Green *et al.*, 2007; Futh *et al.*, 2008) and adolescence (Scott *et al.*, 2011), and with less sensitive parenting in both periods (Scott *et al.*, 2011; Matias *et al.*, 2013). Some aspects of parenting, however, are not emphasized in attachment accounts of parenting, such as cognitive stimulation or consistent discipline; yet studies of child (Matias *et al.*, 2013) and adolescent (Scott *et al.*, 2011) security found that consistent discipline independently predicted secure attachment, beyond sensitive responding. Intervention programs designed to increase attachment security could beneficially target limit-setting as well as sensitive responding (O'Connor *et al.*, 2013).

Biological effects of parenting

Besides affecting children's psychological processes, parenting influences a wide array of biological processes. Physiologically, harsh and abusive parenting often leads to altered stress hormone levels, with chronically elevated cortisol and much greater secretion in response to threat or stress, with slower rates of return to normal levels (see Chapters 23 and 29). Moreover, inflammatory responses are elevated in those who are abused and depressed (see Chapters 29 and 30), and harsh parenting is associated with structural brain changes (see Chapters 23 and 29). Finally, a series of elegant studies in rats led by Meaney and in chimpanzees by Suomi have shown that changes in parenting lead to epigenetic changes (notably acetylation and methylation) in sections of genes that control protein synthesis (see Chapter 25).

The implications of these biological findings for parenting interventions are not yet clear. The physiological changes may be partly reversible by intervention, thus children taken away from abusive parenting into foster care show improved cortisol secretion patterns (Fisher *et al.*, 2006). Whether improving the parenting environment leads to measurable epigenetic or brain changes is uncertain at present. Even if biological changes are alterable, they may contribute to behavioral traits that reduce susceptibility to improved parenting, a subject we now address.

Child characteristics that may affect susceptibility to the effects of parenting

Some child disorders and traits have high heritability, for example, ADHD, autism, and callous-unemotional traits, leading some to assume that they are less susceptible to intervention efforts. However, as we shall see, this is not always the case.

Inherited characteristics and behavioral phenotypes

The effects of parenting can differ according to the characteristics of children. Adoption studies are one way of investigating this (see Chapter 24). In a large follow-up study, Bohman (1996) divided early adopted infants into those whose birth parents had been criminal or alcoholic, representing higher congenital (genetic plus early environmental) risk, versus those who were not. Adopting parents were categorized the same way, to index more and less favorable child-rearing conditions. Police contact by age 17 was 3% versus 12% for children with low versus high congenital risk favorably reared, suggesting a substantial inherited component under good conditions. For those raised under unfavorable conditions, the rates were 7% and 40% respectively. This study, replicated since, shows that some children have a much greater liability to poorer outcomes under stressful rearing conditions, a so-called diathesis-stress model. An implication is that higher congenital risk does not necessarily condemn a child to poor outcomes, indeed improving parenting may have larger effects with such individuals. Moreover, better parenting can help mitigate congenital risk through attachment security. Bergman *et al.* (2010) showed that mothers who had higher amniotic fluid cortisol levels had infants with poorer cognitive development at 17 months, but this effect disappeared if the infant was securely attached.

Longitudinal observational studies suggest that children with different characteristics may need different parenting styles. Kochanska (1997) reported that, for temperamentally fearful children, gentle parental control was associated with optimal behavioral/emotional regulation whereas temperamentally more aggressive (“fearless”) children required firmer control to achieve the same positive results, a finding that has been replicated for children with difficult/irritable temperament, who fare better under conditions of firmer control (Bates *et al.*, 1998).

More recently, the possibility has been explored that rather than just confer liability to poorer outcomes under stressful rearing, some child characteristics may also confer liability to

better outcomes under benign conditions, the so-called differential susceptibility hypothesis (Ellis *et al.*, 2011), whereby some children are relatively impermeable to their surroundings while others are more sensitive. Experimentally, Scott and O'Connor (2012) found that antisocial children who were more emotionally dysregulated (tantrums and anger outbursts) showed a greater response to improved parenting than those who were disobedient in a more controlled way. However, while differential susceptibility is an exciting theory, more replication of findings is necessary to characterize the scope and size of its impact.

These findings have implications for parenting programs. Firstly, intervention effects are likely to vary according to child characteristics— for example, children with autistic traits may change less, whereas those with irritable temperaments may change more. Secondly, parenting programs should not follow a “one size fits all” rigid approach, but rather the content should be varied according to child characteristics.

Specific genotypes

In a classic paper, Caspi *et al.* (2002) found that a variant of a gene coding for an enzyme involved in the breakdown of CNS neurotransmitters Monoamine Oxidase A (MAOA) conferred worse antisocial outcomes in the presence of harsh parenting. The effect has been confirmed in meta-analyses, but it is small. Furthermore, emerging studies identify genotypes that confer differential susceptibility to interventions. However, the field is beset by failure to replicate findings and if found, we will need to know the specific mechanism of action through which such genes exert their effect.

Programs for children with conduct problems

These are almost exclusively based on social learning theory. Characteristics of some of the more widely used programs are given in Table 37.1, the basic content of a typical program in Table 37.2 and pros and cons of a group-based versus individual-based delivery in Table 37.3.

Effectiveness

Outcomes

Programs based on social learning theory have evolved over 50 years and there is a larger evidence base for this intervention than any other psychological intervention in child mental health. The National Institute for Health and Care Excellence (NICE) for England and Wales conducted a meta-analysis of 54 randomized controlled trials (RCTs) of parenting programs for prevention or treatment of conduct problems/disorders in 4150 children aged 3–10 years against any control (43 studies vs. waiting list or no treatment controls, 11 vs. management as usual) (NICE, 2013). The result was a moderate effect size of 0.54 SD on parent-rated outcomes, 0.40 SD by independent observation, and 0.69 SD by independent researcher evaluation. Follow-up 1 year later showed persistent effects but a halving of

Table 37.1 Characteristics of some widely used programs.

Name	Target population	Levels and delivery modes	Evidence	Comments, website, dissemination
Incredible Years	A series of parent group programs from babyhood to age 12	<i>Universal prevention</i> : 6 weeks <i>Indicated prevention</i> : 14 week <i>Treatment</i> : 18–24 weeks	50 RCTs, 10 by developer, 40 independent replications confirm effects	Developer Carolyn Webster-Stratton. One of the most intensive programs in clinical process and supervision www.incredibleyears.com
Triple P	A range of programs at all levels and ages	<i>Universal prevention</i> : On line; broadcast media <i>Selective prevention</i> : short one off sessions up to 4 weeks <i>Indicated</i> 6–8 weeks	Over 50 RCTs by developer; 3 independent replications, some failing to show effects	Developer: Matt Sanders. Comprehensive range of levels www1.triplep.net/
Parent–Child Interaction Therapy	Child disruptive and parenting difficulties including maltreatment	Parent/child dyad is live coached by therapist over 12–20 sessions.	Several RCTs by developer and independent evaluators show effects	Developed by Sheila Eyberg. www.pcit.org/
Parent Management Training Oregon	Behavioral problems age 4–12; parents with mental health problems or separating	Individual program: 19–30 sessions, Group: 14 sessions	RCTs by program developer and independents show effects	Developer: Marion Forgatch. http://evidencebasedprograms.org/1366-2/
Strengthening Families (10–14)	Universal preventive program for age 10–14	Seven 2 hour sessions which include whole family and separate parent and child groups.	Two RCTs by program developer show some effects	Developer Karol Kumpfer. Well developed across many countries www.strengtheningfamiliesprogram.org/
Nurse Family Partnership	Preventive for young, disadvantaged first time mothers	Trained nurses visit mother at home during pregnancy and first 24 months of child's life	Three RCTs have shown varied and long-lasting effects	Developer: David Olds. www.nursefamilypartnership.org

Table 37.2 Content of a typical social learning program.**Part 1: Promoting a child-centered approach**

Play is covered in the first 2–3 sessions. Instead of giving directions, teaching, and asking questions during play, parents are instructed simply to give a running commentary on their child's actions. Parents are asked to practice these techniques for 10 minutes every day

Part 2: Increasing acceptable child behavior

Praise and Rewards. The parent is required to praise their child for lots of simple, desirable everyday behaviors such as playing quietly on their own, eating nicely, getting dressed the first time they are asked, and so on. Later sessions go through the use of reward charts.

Part 3: Setting clear expectations

Clear Commands. Parents are taught to reduce the number of commands, but to make them much more authoritative. The manner should be forceful (not sitting down, timidly requesting from the other end of the room; instead, standing over the child, fixing him in the eye, and in a clear firm voice giving the instruction). Commands should specify what the parent *does* want the child to do, not what he or she should *stop* doing (“please speak quietly” rather than “stop shouting”).

Part 4: Reducing unacceptable child behavior

Consequences for unacceptable behavior should be applied as soon as possible. They must always be followed through and simple logical consequences are encouraged: if water is splashed out of the bath, the bath will end; if a child refuses to eat dinner, there will be no pudding; etc.

Ignoring This sounds easy but is a hard skill to teach parents. Whining, arguing, swearing, and tantrums are not dangerous and can usually safely be ignored. The technique is very effective.

Time Out from positive reinforcement remains the final “big one” as a sanction for unacceptable behavior. The child is put in some boring place for a previously agreed reason (hitting, breaking things, etc —not minor infringements) for a short time (say 5 min). However, the child must be quiet for the last minute.

their magnitude. Interestingly, there was no generalization to the school setting—overall, for all programs, teacher ratings showed no change. No adverse effects or harms were recorded. However, it may be that modest changes in teacher-rated behavior occur with some more intensive programs—for example, a recent

meta-analysis (Menting *et al.*, 2013) of 50 trials of Incredible Years found a small but significant effect on classroom behavior (0.13 SD). Similar findings for parent-reported outcomes were reported in other meta-analyses, for example, by Cochrane Collaboration (Furlong *et al.*, 2012). The latter also analyzed

Table 37.3 Pros and cons of delivering parenting programs in individual versus group format.

Individual	Group
<p><i>Case selection</i></p> <p>Can take on special cases unsuitable for groups: shy parents, failed group parenting programs, high risk/abusive parents</p>	<p>Can take on a variety of cases, can be hard to stop some parents falling behind.</p>
<p><i>Depth of work</i></p> <p>Therapist can go into greater depth of skills that need to be taught</p> <p>Can observe parent interacting with child and pick up styles they are unaware of</p> <p>Can adapt the program for particular child needs for example, attachment problems, autistic tendencies, learning disabilities, ADHD etc</p>	<p>Less detailed due to time constraints and exposure to other parents</p> <p>Restricted to parents' accounts of what goes on with the child.</p>
<p><i>Flexibility</i></p> <p>Flexible order of delivery of program, for example, time out can be given early</p> <p>Flexible timing to attend to suit parent</p> <p>Can easily be delivered in the home context,</p> <p>No need to set up a crèche for child</p>	<p>Fixed order—for example, Limit-setting and time-out have to wait till end</p> <p>Groups held at a fixed time when parent may be busy</p> <p>Parents have to come to clinic or community venue</p> <p>May need to set up a crèche</p>
<p><i>Support from other parents</i></p> <p>No support from other parents</p>	<p>Other parents can provide validation for their efforts; normalize having a child with problems; enable parents to learn from and support each other</p>
<p><i>Therapists skills and support</i></p> <p>Can work as a solo therapist</p>	<p>Requires a second group leader plus group management skills</p>
<p><i>Duration and cost-effectiveness</i></p> <p>Typical program takes around 8 sessions, more complex 10–12</p>	<p>Triple P level 4 has 4 group sessions plus 4 phone sessions; IY minimum 14 sessions, 18–22 recommended for clinical cases</p>
<p>Cost will vary, typically £2000/€2200/\$2500</p>	<p>Costs typically lower per case, £1200/€1350/\$1800</p>

impacts on parental mental health and found it improved by 0.36 SD. Positive parenting and harsh practices improved, assessed by both parent report and independent observation. It is less clear how the effects are sustainable in the long term: many trials have used waiting list control groups that are offered the intervention 6 months later. As a result, no long-term randomized comparison can be made (e.g., Gardner *et al.*, 2006; Bywater *et al.*, 2009). A small number of trials based on selective prevention samples have retained their randomized control group and show good long-term outcomes (Forgatch *et al.*, 2009). In summary, there is convincing evidence that parenting programs substantially improve parenting practices, parental mental health, and child antisocial behavior, and importantly that behavior change is reported both by parent report and independent observations. The evidence for longer-term effects is less conclusive.

Comparison with nonbehavioral programs

There have been rather few head-to-head comparisons of social learning theory parenting programs with nonbehavioral, humanistic approaches. For children with severe conduct problems, the classic paper by Bank *et al.* (1991) found that behavioral parent management training was effective whereas usual family therapy was ineffective on objective measures, despite favorable reports from parents. Most other studies have found that the humanistic approach usually had no effect

whereas the more behavioral programs changed child outcomes (Scott, 2008). A trial of a universal parenting program based primarily on emotional communication (the Family Links Nurturing Programme) found no effects on parenting or child behaviour (Simkiss *et al.*, 2013). It would appear that for child behavior problems, programs with a practical slant and strong focus on parental behavior change are more effective.

Programs for infants

Most programs draw on attachment theory and in the last 20 years or so, several interventions have been developed and validated (see Chapter 6). The more effective interventions for infants typically last 8–20 sessions and videotape parent–infant interactions and then replay them to the parent. The great strength of this approach is that (i) it allows parents to get an accurate picture of what is actually happening (rather than just talking about their perception of their relationship with their infant, as in traditional parent–infant psychotherapies); (ii) it enables them to observe for themselves that when they change their behavior, this impacts on their infant (iii) it allows simultaneous exploration of the mother's mental state, so that mental blocks to more sensitive responding can be explored and often overcome. The Leiden group has tested video feedback programs in RCTs (Velderman *et al.*, 2006).

The Attachment and Biobehavioral Catch-up (ABC; Dozier *et al.*, 2012) is another well-proven intervention. It targets three issues known to affect children's attachment and self-regulation. First, parents are helped to behave in nurturing ways when children are distressed. Second, similarly to social learning approaches, parents are helped to follow children's lead, to enable children to better regulate their emotions. Third, parents are helped to reduce frightening behavior as it is associated with disorganized attachment. These issues are targeted through 10 sessions implemented in families' homes with parents and children present. Other attachment-based programs are discussed in Chapter 6.

Some interventions for infants do not use video-feedback. They include more lengthy and intensive psychodynamic ones, for example, Slade *et al.* (2005). Olds (2006), by contrast, developed a home visiting program delivered by nurses (Nurse Family Partnership), based not on attachment theory but on systematic evaluation of, and evidence-based interventions for, risk factors from pregnancy to age 2 years. Thus parents are encouraged to reduce smoking and alcohol in pregnancy through understanding the effects on their babies; once the baby is born, parent-child interaction is coached, including how to stimulate the baby appropriately, and wider issues such as partner violence and general education for the mother are addressed.

Effectiveness

A meta-analysis by Bakermans-Kranenburg *et al.* (2003) found 81 studies, with over 7000 parent-infant pairs. Overall, they improved parental sensitivity by 0.33 SD and attachment security by 0.20 SD. The most effective interventions were relatively short (under 26 sessions) and started later (after the infant was 6 months). Both of these findings go against cherished notions that early intervention must be better, and that more effort should lead to more change (mean effect size for long interventions was -0.03). Recently, an RCT of the Attachment and Biobehavioural catch up (ABC) intervention showed that as well as enhancing child attachment security, it improved diurnal cortisol production, executive functioning, and emotional regulation (see Chapter 6).

For programs that do not rely on attachment theory, those that focus on specified risk factors appear to fare better. Thus the Nurse-Family Partnership approach has been evaluated in three RCTs involving over 1000 mother-infant pairs. This has shown benefits for the child in terms of improved cognitive and emotional development and fewer accidents and injuries, and for the mothers in terms of less harmful health behaviors (e.g., smoking) and higher take-up of further education, less use of public handouts, and a longer interval until subsequent pregnancy (Olds, 2006). By contrast, programs that draw upon a more general notion that if the parents are supported, then they in turn will relate better to their infants appear less effective. For example, in a trial of a home visiting program with 97 hours of face-to-face contact with mothers, none of the many mother or child variables measured changed (Barnes *et al.*, 2006); a

similar lack of effectiveness was found for the Oxfordshire Home Visiting project (Barlow *et al.*, 2007).

Father involvement in parenting programs

Most literature refers to "parenting" as if it made no difference whether fathers or mothers were involved. While in the great majority of cultures it is more often mothers who spend most time looking after younger children, fathers have a particular role, which often increases as children become older (Lamb, 2004). When it comes to parenting programs, it should not necessarily be assumed that evidence about effectiveness applies equally to mothers and fathers. In practice, however, it is mainly mothers who attend parenting programs and participate in research evaluations. The under-representation of fathers in these interventions is perhaps surprising, given that in many countries their role now reflects greater equality of gender roles and increased sharing of parenting (Maughan & Gardner, 2010). Furthermore, there is considerable research suggesting that amount and quality of father involvement in parenting is beneficial to children's mental health and development, over and above the level of the mother's involvement (Lamb, 2004; Ramchandani *et al.*, 2013). A systematic review by Lundahl *et al.* (2008) suggested that if intervention trials involve fathers, they produce stronger effects on child behavior. Some interventions have been designed to engage couples and fathers, with improved outcomes when couples attend (Cowan *et al.*, 2009). However, as it would be very difficult to randomize to one versus two parents attending a program (but see Besnard *et al.*, 2013), it is unclear if father attendance *per se* causes these changes, or whether outcomes are better in families with two parents (as found by Gardner *et al.*, 2009), and in families where the couple relationship is healthier (Cowan *et al.*, 2009), so fathers are more likely to attend. Irrespective of trial data, it is highly desirable that interventions should involve both parents. Studies of fathers' views (Stahlschmidt *et al.*, 2013) suggest a number of barriers (and potential solutions), including time of day of the intervention, and that many interventions are run by women, who may find it easier to communicate with mothers than fathers. This effect can be pronounced in group-based interventions where fathers may feel out of place if they are in a minority.

Application of programs to specific populations

Although designed for conduct problems, these programs can improve other clinical outcomes, even with minor or no adaptation; they can reduce children's anxiety disorders (Cartwright-Hatton *et al.*, 2011), ADHD (Jones *et al.*, 2008; Charach *et al.*, 2013); obesity (Brotman *et al.*, 2012), and parental depression (Hutchings *et al.* 2007; Barlow *et al.*, 2012).

However, adaptation and extension of these parenting programs is now increasingly occurring for a range of child psychiatric problems and parental contexts.

Programs for particular child issues and contexts **Depression, anxiety, and other emotional problems**

Evidence supporting a link between quality of parent–child relationships and depression, anxiety, and other emotional problems (e.g., somatic complaints and social withdrawal) is clear, although smaller than that found for disruptive outcomes (Dadds *et al.*, 1996; Wood *et al.*, 2003). Low warmth and conflict are both linked with depression and anxiety; however, the influence of control strategies is generally much weaker. Additionally, emotional symptoms in children are linked with over-protectiveness (e.g., Dadds *et al.*, 1996). The elements of parenting programs aimed primarily at conduct problems are likely to be helpful for children showing emotional symptoms, but generally an individual-based intervention should probably be added, although Cartwright-Hatton *et al.* (2011) tested the effects of a group-based parenting program for diagnosed clinically anxious children (aged 3–9) and found strong effects on reducing anxiety disorders. The majority of sessions focused on components of traditional social learning theory-based parent management skills (e.g., child-centered play, rewards, and limit setting), with about one third of the sessions focusing on components specifically aimed at dealing with anxious children (e.g., anxiety education; fear hierarchies).

ADHD

A number of parenting programs designed for conduct problems have shown improvements in ADHD symptoms as well (Scott *et al.* 2001, 2010b; Webster-Stratton, 2011; Charach *et al.*, 2013). Additionally, parenting interventions have been developed specifically for children with ADHD, for example, the New Forest program in the UK, which showed good effects on ADHD symptoms in preschoolers in a clinic-based trial, but not in routine services (Sonuga-Barke *et al.*, 2001). Recent systematic reviews conclude that behavioral parenting interventions are effective for younger children with ADHD, more so than methylphenidate (Charach *et al.*, 2013), and are probably effective for older children (Zwi *et al.*, 2011). European and UK (NICE) guidelines, both recommend parenting programs as the first line treatment for ADHD. However, Sonuga-Barke *et al.* (2013) found that while effects were good on parent-report, they were negligible using direct observation.

Callous unemotional traits

Despite the common belief that children with conduct problems who also show callous unemotional traits are insensitive to parenting, and to parenting interventions, Waller *et al.* (2013) found little evidence to support this belief, either from longitudinal studies or from randomized trials. Nevertheless,

specific programs are being developed for them (Dadds *et al.*, 2013).

Programs for particular parent issues and contexts

Specific parental issues and contexts

There is some promising evidence that social learning theory based programs, with some adaptation and extension, can be effective for parents who maltreat their children (MacMillan *et al.*, 2009; Ch 30). For drug misusing parents, the program “Parents under Pressure” has shown promising results (Dawe & Harnett, 2007). For children in the foster care system, some trials suggest that parenting interventions aimed at foster-caregivers, can be effective in reducing problem behavior in this often very troubled group of young people (Briskman & Scott, 2013), although other trials have been more disappointing (MacDonald & Turner, 2005; Turner *et al.*, 2007), perhaps where the interventions have been less intensive.

Transportability of parenting programs to different cultures and countries

Parenting programs appear to transport well across cultures, despite different parenting norms and values. A systematic review of programs developed in the USA and Australia found comparable effect sizes in recipient countries, including Europe and Asia (Gardner *et al.*, 2015). Surprisingly perhaps, in many cases, “imported” programs were more effective in culturally very different settings (for example, Hong Kong). These findings are consistent with studies of effects in ethnic minority groups within one country. For example, Reid *et al.* (2001), in a large study of low income families in the USA found no ethnic differences in outcomes, engagement, or satisfaction across four ethnic groups, and Scott *et al.* (2010a) found a similar lack of ethnic differences in outcomes in London.

Given the high levels of international concern about youth crime and violence in developing countries (WHO, 2013), and the loss of children’s developmental potential due to poverty and conflict, it is important to know if parenting programs work in low and middle-income countries (LAMICs). A recent systematic review (Knerr *et al.*, 2013) found promising evidence from randomized trials that parenting programs can be effective in LAMICs for improving harsh parenting, and potentially for reducing conduct problems. Broader parenting interventions that also target early cognitive stimulation can also be effective for improving parenting skills and children’s developmental potential (Engle *et al.*, 2007; Rahman *et al.*, 2009). WHO (2013) have begun an important initiative to develop, adapt, and test through RCTs programs in LAMICs, where home-based parenting interventions have already shown good results for infants (Cooper *et al.*, 2009; Knerr *et al.*, 2013). There are many other examples of promising practice in developing countries, but very few have been tested in rigorous trials (Knerr

et al., 2013), as recommended by WHO, and sustainability will be challenging.

What makes parenting programs work?

Predictors and moderators of outcome

In a controlled trial, if a characteristic of the participants (e.g., child age or symptom severity) predicts outcome in both the intervention and control groups, then it is a predictor. If, however, there is an interaction with treatment, so that one subgroup (say younger children) does better than another (older children) in the intervention group only, then the characteristic is operating as a moderator. Until recently, analyses have mainly been at the level of predictors only, with one or two exceptions. It is crucial that treatment and policy decisions are based on evidence from moderator, rather than predictor analyses. Without these comparisons between intervention and control group, it is not possible to tell if a group that appears to benefit to a greater extent from treatment (e.g., girls or younger children), would not have done equally well untreated.

Child age and gender

Clinicians often gain the impression that boys and older children, especially adolescents, perform worse, and Bank *et al.* (1991) found a smaller effect size with adolescents than with younger children at the same institution. However, meta-analyses of interventions for antisocial behavior are mixed. For example, the Cochrane reviews of parenting interventions for antisocial behavior found an effect size of 0.56SD in teenagers (Woolfenden *et al.*, 2001), 0.53SD in middle childhood (Furlong *et al.*, 2012) and 0.25SD in early childhood (Barlow *et al.*, 2010), thus showing *smaller* effects in younger children. Within the middle childhood age range, Furlong *et al.* (2012) found no effect of age on outcome. Teenagers may appear less tractable for a number of reasons. Firstly, many studies on adolescents include the most severe cases (Lipsey, 2003; Leijten *et al.*, 2013). Often, when severity is controlled for, there is no age effect—across a wide age range (2–16 years), Ruma *et al.* (1996) found that the adolescent group did slightly less well, but the difference disappeared after taking into account initial severity. Within prepubertal children, there also do not appear to be age effects when using direct observation (Dishion & Patterson, 1992; Beauchaine *et al.*, 2005). By contrast, the meta-analysis by Serketich and Dumas (1996) found that across (not within) 36 studies ranging from 3 to 10 years, effectiveness was *greater* in older children. In summary, it appears that age is not a clear determinant of outcome. Likewise, boys are as likely to improve as girls (e.g., see Beauchaine *et al.*, 2005; Scott, 2005). Therefore, there is room for some optimism when treating adolescents.

Child psychopathology

The meta-analysis by Reyno and McGrath (2006) found that more severe initial antisocial behavior predicted (not

moderated) *less* change, but this was a bivariate association with no controlling for other factors. By contrast, taking other factors into account, Scott (2005) found the opposite, namely that higher initial levels of antisocial behavior predicted more change. Most recent reviews and meta-analyses tend to concur. Although Furlong *et al.*'s (2012) Cochrane review found no difference by conduct problem severity (coded at the trial level), Shelleby & Shaw's (2014) narrative review, and meta-analyses by Lundahl *et al.* (2006) and Leijten *et al.* (2013) found larger effect sizes with higher initial severity. Future studies need to address this issue using multivariate statistics and larger pooled samples. Child ADHD predicts a less good response in some studies (MTA, 1999; Scott, 2005) but not others (Beauchaine *et al.*, 2005; Ollendick *et al.*, 2008). In the MTA study, direct observations in the psychological treatment-only arm showed that parents had changed their behavior, whereas child ADHD symptoms had not (Wells *et al.*, 2006). This suggests that it is the characteristics of the children with ADHD that make them less sensitive to change, rather than parents not implementing more effective parenting practices. By contrast, when studied, comorbid anxiety appears to predict better treatment response for children with behavior problems (Beauchaine *et al.*, 2005). A broad review by Ollendick *et al.* (2008) concluded that for conduct problem interventions, comorbidity did not affect outcomes.

Family factors

Demographic predictors of outcome such as single parenthood, lower maternal education, poverty, and larger family size have traditionally been found in meta-analyses to have a small but negative effect on outcomes (Lundahl *et al.*, 2006; Reyno & McGrath, 2006). However, a recent systematic review (Leijten *et al.*, 2013) that controlled for confounders, especially initial child problem severity, found no diminished effects of parenting interventions in low socio-economic status families, consistent with moderator analyses in recent trials of more flexible interventions (Dishion *et al.*, 2008; Gardner *et al.*, 2009, 2010).

Similarly, reviews have traditionally found that parental psychopathology, especially maternal depression, predicts worse outcomes, as do life events and harsher initial parenting practices (Reyno & McGrath, 2006). However, Gardner *et al.* (2010) found *larger* child improvement with depressed parents. For mothers with the most negative beliefs about their children, Doolan (2006) found no change in child behavior at all. Overall, these conflicting subgroup findings from small trials suggest that the field would benefit from pooling individual patient-level data from multiple randomized trials (Brown *et al.*, 2013).

Mediators of change

In recent years, researchers have begun to investigate what mediates outcome, as recommended by Rutter (2005). To mediate treatment outcome, the treatment has to (i) change outcome (ii) change the mediator (iii) the mediator has to correlate with outcome, and (iv) the effect of treatment on outcome has to

reduce or disappear after controlling for the mediator (Kraemer *et al.*, 2002). It would seem likely that for parenting programs to change child behavior, some aspect of parenting would first have to change. This is worth testing as it might not be the case—for example, the parenting program could make a couple realize that they should for example, stop arguing in front of their child, but still use the same disciplinary strategies.

Beauchaine *et al.* (2005) and Tein *et al.* (2004) found that changes in critical and ineffective parenting mediated child change in antisocial behavior, whereas several studies have found that positive parenting mediated change (Gardner *et al.*, 2006, 2010; Dishion *et al.*, 2008). Gardner *et al.* (2006) tested competing mediators, finding that it was change in positive parenting skill, rather than confidence in parenting, that predicted change in child problem behavior. In adolescents, Eddy and Chamberlain (2000) found for parenting, quality of supervision and discipline, and a positive adult–youth relationship all mediated change, as did time spent with deviant peers and the degree of their influence. Taken together, these four factors accounted for a substantial 32% of variance in subsequent antisocial behavior. Similarly, Huey *et al.* (2000) in a trial of MultiSystemic Therapy for delinquency showed that a positive relationship and firm discipline mediated outcome and good supervision mediated deviant peer association which in turn mediated subsequent antisocial behavior. These studies indicate which variables need to change for a good outcome and have led to changes in programs, for example, there is now a much stronger emphasis on preventing deviant peer association—the OSLC Treatment Foster care program penalizes youth for every minute that they cannot verifiably account for their whereabouts.

Implementation and dissemination

Implementation

Most of the trials cited earlier were carried out using (i) specially recruited cases rather than clinical referrals, (ii) specially trained research therapists rather than regular clinicians (iii) university rather than clinical settings; indeed Weisz's studies show that fewer than 5% of psychosocial child mental health trials meet all three “real-life” criteria (see Chapter 36). There is therefore considerable concern whether the good effects seen in trials will be replicated in everyday life, where cases have a high degree of comorbid conditions and most therapists do not use evidence-based approaches and do not get skill-specific supervision. Trials that compared evidence-based approaches in real-life with usual services nonetheless get a clear advantage, by 0.3 SDs (see Chapter 36). The challenge is therefore to disseminate best practice more widely and to ensure that it is well implemented (Fixsen *et al.*, 2011).

Therapist effects

Therapist performance can be divided into three elements. (i) the *alliance*, which includes how well client and therapist get on together and agree shared goals. A meta-analysis of youth

studies of the alliance found it contributed on average an effect size of 0.21 SD to outcome (Shirk & Karver, 2003). (ii) *fidelity* or adherence to specific components of a model that concerns the extent to which the therapist follows the actions prescribed in the manual. In a large real-life study of the implementation of a family program for antisocial youths, Sexton and Turner (2011) found that therapists who were highly adherent to the model obtained good results, with a larger effect size on more severe cases, whereas low adherent therapists actually obtained poorer results than the control group, implying that they might have perpetrated harm. (iii) the *skill* or competence with which the therapist carries out the tasks, that is, how well the therapist performs the actions. Skill can include aspects of the alliance and fidelity. Both Forgatch *et al.* (2005) and Eames *et al.* (2009) found that therapist skill significantly predicted change in independently observed parenting. In summary, there is good evidence that therapist variables make a crucial difference to parenting programs for antisocial behavior.

Dissemination

Although formal surveys are lacking in most countries, from the paucity of professionals trained in evidence-based programs, we can conclude that the vast majority of children with conduct problems or insecure attachment are not offered proven approaches. There are examples of initiatives to address this. Norway has set up a national training center to roll out and support a portfolio of parenting programs. In England, the National Academy for Parenting Practitioners was set up in 2007 and by 2010 had trained 4000 practitioners in a small number of carefully chosen evidence-based programs, estimated to have benefited 150,000 children (Scott, 2010). This was accompanied by a sizeable research program and a detailed evaluation of over 100 parenting programs, with the results posted on a searchable site for parents and commissioners (www.education.gov.uk/commissioning-toolkit). For clinically referred cases, the Children and Young People's Increasing Access to Psychological Therapies (CYP-IAPT) initiative is training up 5 staff from each local health authority in England in either parent training for conduct problems or cognitive behavioral therapy (CBT) for depression and anxiety. The training is intense, 3 days a week over a year, with close supervision of skills. A further element likely to lead to effectiveness is insistence on session-by-session outcome monitoring (<http://www.iapt.nhs.uk/cyp-iapt>). More is now known about how to achieve successful dissemination, including training managers as well as clinicians, educating both that regular supervision is necessary, and making the case for the cost-effectiveness of parenting programs.

Prevention

In an ideal public health preventive strategy, all parents would learn effective parenting skills, which would help to improve

parent–child relationships and child well-being, and reduce the population rate of harsh and abusive parenting. There would be a tiered set of interventions available in primary and then in increasingly specialist levels of care, to help those with continuing difficulties. This vision has been well articulated by Sanders (1999) and appropriate programs developed by his group for each level. It is clear that we have good evidence for the effectiveness of parenting interventions for selective and indicated prevention and for treatment of conduct problems. However, it is less clear whether universal prevention parenting programs work: there have been many successful trials, but also many unsuccessful ones (Malti *et al.*, 2011; Simkiss *et al.*, 2013). Further studies need to understand under which conditions and using which delivery mechanisms, universal parenting programs can be helpful; if they are not, then the conclusion might be that targeted programs are more useful. Prevention is covered in more detail in Chapter 17.

Conclusions

Parenting programs have developed considerably in recent years. Findings from scores of randomized trials present a positive view of their effectiveness, with widespread implementation in many countries. Recent moderator analyses suggest that for many groups considered as hard-to-treat, for reasons of social disadvantage or psychopathology, parenting interventions can improve child behavior. For families with very complex needs, such as those in the child protection system, the evidence is promising. Future developments need to include evaluation of the long-term effects of programs and the mechanisms that mediate changes in parenting behavior. As parenting programs tend to have small effects on children's behavior in school, further evidence on school-based programs is warranted. Finally, future studies need to investigate which families can improve with minimal intervention such as computer-based self-instruction.

CHAPTER 38

Cognitive-behavioral therapy, behavioral therapy, and related treatments in children

Philip C. Kendall, Jeremy S. Peterman and Colleen M. Cummings

Department of Psychology, Temple University, Philadelphia, PA, USA

Understanding cognitive-behavioral therapy (CBT)

Cognitive-behavioral therapy (CBT) represents an integration of both cognitive and behavioral models of psychopathology. Given that CBT expanded from behavior therapy (BT), behavioral theories are a starting point in understanding CBT. In the 1930s, behaviorism emerged as a reaction to introspective psychology (e.g., examination of one's own conscious thoughts and feelings). Behavioral theories de-emphasize the "active mind" and consciousness as these phenomena cannot be readily observed or measured, and hold that environmental events shape behavior. For example, in respondent conditioning, youth learn behavior through associations. When a feared stimulus (unconditioned stimulus) is temporally paired with a neutral stimulus (conditioned stimulus), the initially neutral stimulus consequently provokes a fear response, even when presented in isolation. Therapeutic strategies born from respondent conditioning, such as extinction (presenting the conditioned stimulus without the unconditioned stimulus), and habituation (experiencing the conditioned stimulus over a prolonged period of time) have been integrated into treatment.

Operant conditioning (Skinner, 1969) marks a cornerstone in BT. Operant learning theories are based on learning due to consequences from a response (e.g., an increase or decrease a specific behavior via reinforcement and punishment, respectively). For example, an oppositional youth may act out to receive attention. When the parent attends to the behavior, by acquiescing to the youth's demands, the youth's behavior is reinforced and is likely to remerge in the future. On the other hand, when the parent provides reinforcement (e.g., praise)

for a counter-behavior, prosocial behaviors may increase over time. Thus, reinforcement (and punishment) can be both the problem and solution and is utilized within CBT. A common way that reinforcement is integrated is through shaping, in which a complex behavior is broken into several simpler steps and completion of each small step is rewarded.

CBT evolved from BT with the addition of cognitive theory. Cognitive theory emphasizes the importance of social information-processing (e.g., memory, attention, and flexible thinking) and cognitive distortions in psychopathology. Thus, cognitive theory brought "mind" back to psychology, positing that one's interpretation and processing of stimuli and events impact behavior. Specific theories regarding the latter have been pioneered by Aaron Beck and Albert Ellis. Though using different language, Beck and Ellis converge on the idea that cognition mediates the relationship between life stress and psychopathology. Rigid and distorted beliefs about oneself, the world, or the future are accordingly targeted in cognitive therapies. In other words, altering one's belief system can modify behavior. Additionally, the influence of information-processing theory has translated to therapies that target problem solving skills. CBT was also influenced by Bandura (1977) who described how learning can occur through observation. Observational learning has influenced specific CBT techniques, such as modeling and role-play.

Overall, CBT and BT are grounded in complementary theories that explain the psychology behind the emergence of psychopathology. Accordingly, CBT has developed a set of treatments, derived from behavioral and cognitive theory, to treat psychopathology. CBT has evidenced success across many diagnostic categories. In the following section, some of the supporting evidence will be considered.

Empirically-supported CBTs and BTs for youth

Several CBTs, BTs (and some other treatments) for youth psychopathology have emerged as having varying levels of empirical support (Kendall, 2012) according to guidelines by Chambless and Hollon (1998) and Chapter 36.

Treatment modalities

CBT and BT may be provided in individual, group, or family-based modalities. Individual treatment optimizes personalized treatment. Group treatment increases “reach” by working with multiple youth at a time, with opportunities for social skills practice and the ability to complete therapeutic activities (e.g., exposure tasks) with the support of peers. Treatment must still meet the individual needs of each group member and may not be indicated for children with multiple comorbidities (e.g., Farrell *et al.*, 2012), environmental stressors, or other characteristics that decrease participation in group therapy (e.g., severe social anxiety or antisocial behaviors). Family-based treatment can target familial patterns and parenting practices that may serve to maintain youth psychopathology if not adequately addressed. Typically, youth CBTs and BTs include some form of parental involvement, which can vary from a few parent sessions to family-based treatment. Overall, the degree to which family members participate in youth treatment may depend on several factors (e.g., presence of a parental psychological disorder; maladaptive parenting behavior and family patterns; Creswell & Cartwright-Hatton, 2007).

Anxiety disorders

CBT for youth with anxiety is a well-established treatment (Hollon & Beck, 2013). Individual treatments are common for child anxiety. One is the *Coping Cat program* (Kendall & Hedtke, 2006a, b). It consists of 16 sessions, separated into two segments: skills training and skills practice (exposure tasks) and has been adapted for adolescents (i.e., *The C.A.T. Project*; Kendall *et al.*, 2002). Several RCTs have supported its efficacy (Walkup *et al.*, 2008). Additionally, gains have been found to be maintained at 1-year to 7.4-year follow-ups, and a meaningful percentage of successfully treated participants had reduced problems associated with substance use (Kendall *et al.*, 2004; Puleo *et al.*, 2011).

The largest randomized controlled trial (RCT), the Child/Adolescent Anxiety Multimodal Study (CAMS), evaluated the efficacy of CBT (the *Coping Cat/ C.A.T. Project*), medication (sertraline), a combination of the two (COMB), and a pill placebo (PBO) among 488 youth (ages 7–17). 80% of COMB (effect size = 0.86), 60% of CBT (effect size = 0.31), 55% of sertraline (effect size = 0.45), and 24% of placebo were considered treatment responders (rated by independent evaluators) at week 12 (Walkup *et al.*, 2008). Rates of remission (i.e., identified as almost symptom-free) were lower but demonstrated the same pattern as rates of response (i.e., 68% of COMB, 36% of

CBT, 46% of sertraline, and 27% of placebo; Ginsburg *et al.*, 2011). The results were maintained at 36 week follow-up, with additional improvement to monotherapy conditions (i.e. 58% of CBT and 63% of sertraline; Piacentini *et al.*, 2014). Data from RCTs suggest predictors: youth with a combination of more severity of symptoms at baseline, a primary diagnosis of social phobia, and comorbid internalizing disorders have a less favorable response to CBT (Crawley *et al.*, 2008; Ginsburg *et al.*, 2011).

Obsessive compulsive disorder

Exposure and response prevention (ERP) for obsessive compulsive disorder (OCD) in youth has been classified as probably efficacious (Weisz *et al.*, 2013). The focus of ERP is to expose youth to stimuli that trigger obsessions, while encouraging the youth to refrain from engaging in compulsions that provide immediate, but transient, relief from anxiety (Foa & Kozak, 1986). The Pediatric OCD Treatment Study (POTS) was a multisite trial for 112 youth, aged 7 to 17, who were randomly assigned to CBT, sertraline, combined CBT and sertraline (COMB), or PBO for 12 weeks. All three active treatments outperformed PBO, and COMB was superior to CBT and sertraline. Furthermore, a greater number of CBT patients entered remission than sertraline patients.

In POTS predictors of attenuated response included higher OCD severity, higher levels of OCD-related functional impairment, higher levels of comorbid externalizing symptoms, and higher levels of family accommodation. Interestingly, family history of OCD moderated the effect of treatment condition: for participants with a positive family history of OCD, there were no differences in outcomes across the treatment groups, whereas for those with no family history, COMB outperformed PBO and SER and CBT outperformed PBO. Additionally, treatment effect sizes were smaller for those with a family history of OCD, and this reduction in effect sizes was particularly high for the CBT group (Garcia *et al.*, 2010). The presence of a comorbid tic disorder moderated outcomes: among patients with a tic disorder, SER did not differ from PBO, whereas COMB remained superior to CBT and CBT remained superior to PBO (March *et al.*, 2007).

Post traumatic stress disorder

For youth with PTSD, exposure-based CBT has been designated as well-established (Weisz *et al.*, 2013). Exposures consist of confrontation with fearful memories of the trauma and can be imaginal or *in vivo*. The components of Trauma Focused-CBT (TF-CBT) are summarized by the acronym “PRACTICE,” including psychoeducation/parenting component, relaxation, affect modulation, cognitive processing, trauma narrative, *in vivo* exposure and mastery of trauma reminders, conjoint child–parent session, and enhancing safety and future development (Cohen *et al.*, 2007; see <http://tfcbt.musc.edu>). TF-CBT has demonstrated efficacy in RCTs. One study compared TF-CBT to child-centered therapy among 229 children (aged 8–14) who had been sexually abused. TF-CBT was superior on almost all

measures, although 21% of children treated with TF-CBT still met diagnostic criteria for PTSD (Cohen *et al.*, 2004).

Depressive disorders

CBT is a well-established intervention, and BT is a probably efficacious intervention for youth depression (Weisz *et al.*, 2013). CBT for depression seeks to identify negative thoughts and encourages behaving in more positive and engaging ways. Core cognitive strategies include self-monitoring (i.e., using a CBT Thought Record), restructuring, and the identification of underlying assumptions. Core behavioral strategies include contingencies, self-reinforcement, activity scheduling, and relaxation training. CBTs that have received empirical support among youth include school-based approaches (Stark *et al.*, 2007) and Primary and Secondary Control Enhancement Training (PASCET; Weisz *et al.*, 1997). Among depressed adolescents, efficacy has been found for a CBT group treatment: the Adolescent Coping with Depression Course (CWD-A; Clarke *et al.*, 2001; Rohde *et al.*, 2001). TADS was a multicenter RCT that compared the effectiveness of fluoxetine alone, CBT alone, CBT plus fluoxetine, and placebo. Results supported the combination treatment (TADS Team, 2004): CBT plus fluoxetine led to the highest rates of response, followed by fluoxetine alone, CBT alone, and finally placebo, with response rates of 71%, 61%, 43%, and 35%, respectively. Adolescents with mild or moderate depression had better results with CBT plus fluoxetine than fluoxetine alone or CBT alone. Patients with severe depression responded equally well to CBT plus fluoxetine and fluoxetine alone (Curry *et al.*, 2006) with maintenance of gains for longer term TADS treatment (36 weeks) to 1-year follow-up (TADS Team, 2009). The Adolescent Depression Antidepressant and Psychotherapy Trial (ADAPT) randomized adolescents to SSRI (fluoxetine) + CBT or SSRI only conditions. ADAPT included participants with moderate to severe MDD and active self-harm. After the acute and maintenance treatment phases, response rates did not differ by condition, with 61% in the SSRI only condition and 53% in the SSRI + CBT rated to be much or very much improved (Goodyer *et al.*, 2007).

What about nonresponders? The Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) randomized adolescents with MDD who did not respond to an 8-week trial of an SSRI to the following conditions: (i) switch to a different SSRI, (ii) switch to venlafaxine, (iii) switch to a second SSRI + CBT, (iv) switch to venlafaxine + CBT. Results indicated that treatment arms that included CBT outperformed medication-only (54.8% and 47% responders, respectively; Brent *et al.*, 2008).

Interventions are more efficacious for adolescents compared to children, albeit most effective for younger adolescents (e.g., Michael & Crowley, 2002). Ethnicity may moderate treatment, and Rohde and colleagues (2006) found that CBT outperformed control for only White youth, whereas non-White adolescents demonstrated no difference across conditions. In terms of gender, it has been suggested that female youth respond better to treatments with an interpersonal orientation (Garber,

2006). Findings suggest that more chronic depression, suicidality, melancholic features, poorer expectations for treatment success, and comorbidity (i.e., anxiety, attention deficit hyperactivity disorder (ADHD), disruptive behavior disorders, and substance abuse) may impede progress in depression treatment (Rohde *et al.*, 2001; Curry *et al.*, 2006).

Bipolar disorder

Treatment guidelines describe psychological treatment as an essential adjunct to pharmacological treatment for children with bipolar disorder. Psychosocial treatment targets psychoeducation, relapse prevention, individual therapy, social and family functioning, academic and occupational functioning, and community consultation (McClellan *et al.*, 2007). Adjunctive psychoeducation teaches families about the symptoms of bipolar disorder as well as its biopsychosocial management (e.g., improving family problem-solving and communication skills). Psychological therapy has demonstrated efficacy for bipolar disorder in youth (West *et al.*, 2007; Fristad *et al.*, 2009) and can be considered a probably efficacious treatment.

Psychosocial treatments that have been evaluated in youth with bipolar disorder include Fristad *et al.*'s work with multifamily psychoeducational psychotherapy groups (MF-PEP; Fristad *et al.*, 2011) and individual family psychoeducation (IFP), Miklowitz *et al.*'s family-focused treatment (FFT), and Pavuluri and colleagues' child- and family-focused CBT (CFF-CBT). These treatments showed improvements in their samples, including increases in parental knowledge of these treatments, lower ratings of symptom severity, improved family climate (Pavuluri *et al.*, 2004; Miklowitz *et al.*, 2008, 2013; Fristad *et al.*, 2009). At this juncture, the efficacy of FFT and MF-PEP is evidenced by RCTs, while empirical evidence of CFF-CBT includes only pilot studies.

Disruptive behavior disorders

A number of treatments for children and adolescents with disruptive behavior disorders (i.e., oppositional defiant disorder; conduct disorder) have garnered empirical support (Eyberg *et al.*, 2008). These are described in depth in Chapter 65 of this volume. Parenting programs alone (see Chapter 37) are well-supported, but individual programs are increasingly being shown to be effective. One CBT, the Coping Power Program (Lochman *et al.*, 2008), is based on a social-cognitive model of aggression (Lochman & Gresham, 2008), taking into account individual and environmental risk factors. Coping Power includes a 34-session child component (delivered either individually or in a group) and a 16-session group parent component. Children learn relaxation, emotion awareness, goal setting, and social skills such as how to manage peer pressure. Parents learn parent training techniques (e.g., positive reinforcement; ignoring), as well as strategies to manage their child's academic environment, family conflict, and their own stressors. RCTs have documented its efficacy (i.e., Lochman & Wells,

2004) and effectiveness (i.e., Lochman & Wells, 2003). Regarding predictors, (McMahon *et al.*, 2006), economic disadvantage and single parent household has been associated with poorer outcomes (Lundahl *et al.*, 2006).

Eating disorders

Adolescent eating disorders typically include anorexia nervosa (AN) and bulimia nervosa (BN) (see Chapter 71). CBT focuses on (i) addressing distorted cognition related to body shape and weight and (ii) working to directly alter maladaptive eating patterns, including restricting and purging. Although examined among samples including younger and older adolescents, CBT in general meets the criteria for an established treatment for BN (Keel & Haedt, 2008). The Maudsley model of family therapy for eating disorders includes the family in treatment (Lock *et al.*, 2001). Keel and Haedt (2008) determined that family therapy was a well-established treatment for adolescent AN (e.g., Robin *et al.*, 1999; Lock *et al.*, 2005) and a possibly efficacious treatment for adolescent BN (e.g., le Grange *et al.*, 2007).

Attention deficit/hyperactivity disorder

Stimulant medication has considerable evidence supporting its use for reduction of ADHD symptoms in youth (see Chapter 55). Nonetheless, BT is recommended as a first line intervention for youth with more mild levels of ADHD (see guidelines by the National Institute for Health and Care Excellence, 2008). For youth with more severe symptoms, BT has its place as a second line intervention or adjunctive intervention to medication that may add to long-term benefit (see guidelines by the American Academy of Child and Adolescent Psychiatry, 2007). BT, rather than CBT and nonbehavioral approaches, has empirical support for youth with ADHD (Pelham & Fabiano, 2008), although a recent meta-analysis suggested limited effect sizes (overall standard mean difference = 0.02) when blinded outcome assessments were used (Sonuga-Barke *et al.*, 2013). Established treatments for ADHD in youth include behavioral parent training, behavioral contingency management in classrooms, and intensive peer-focused interventions (e.g., summer camps).

In the Multimodal Treatment of Attention Deficit Hyperactivity Disorder (MTA) Study (MTA Cooperative Group, 1999a) Children were randomized to either 14 months of medication management (MedMgt), behavior therapy (Beh), their combination (Comb), or usual community care (CC). Findings post treatment (14 months) indicated that Comb and MedMgt showed greater improvements in ADHD and disruptive behavior disorder symptoms than Beh or CC (MTA Cooperative Group, 1999a). Comb outperformed Beh and CC in terms of internalizing symptoms, teacher-rated social skills, parent-child relationships, and reading achievement (MTA Cooperative Group, 1999a). Important to note, at 10-month, 3-year, and 8-year follow-ups, differences among the treatments were no longer apparent (MTA Cooperative Group, 2004a, b; Jensen *et al.*, 2007; Molina *et al.*, 2009).

Behavioral Classroom Management involves contingency management procedures in the classroom and teacher training in discipline procedures. RCTs of behavioral classroom management have demonstrated efficacy (e.g., Pelham & Fabiano, 2008). RCTs of summer treatment programs have also demonstrated efficacy (e.g., Pelham & Fabiano, 2008). Pelham and Fabiano (2008) concluded that due to its chronic nature, ADHD requires long-term, multisystemic, often multi component treatment to ensure long-term gains. There is evidence that low income and ethnic minority families may respond less well (Chronis *et al.*, 2004), but comorbidity and gender each have little association (Pelham & Fabiano, 2008).

Common treatment components

CBT and BTs are time-limited, typically manual-based, present-focused, and require active participation from youth and families. They address current problems rather than exploring early childhood conflicts. However, CBT and BT do take time to understand family interactions and previous traumas that may influence current disorder. Finally, CBT and BT require youth to actively contribute and participate in therapy, including activities between sessions (e.g., homework).

Psychoeducation

Typically an early feature of CBT interventions, psychoeducation involves information about possible explanations for the presenting problem, an overview of the treatment process, and affective education. First, the therapist provides a general framework for understanding the presenting problem. As part of this framework, there is, within reason, an effort to normalize certain emotional difficulties and reduce parent- and self-blame. For example, in the treatment of OCD the brain can be described as “short circuiting,” or for younger youth, “having brain hiccups” (March & Mulle, 1998).

Another aspect of psychoeducation involves an overview of the treatment plan. From the onset, therapists note the subsequent sessions and the goals of therapy, while integrating feedback from the client to tailor the program. An overview of therapy also involves a discussion of each individual's part in the therapeutic process. The therapist may explain his/her own role using the metaphor of a “coach” (Kendall, 2012), in which the therapist provides support, encouragement, and training throughout treatment. Collaboration between the youth and the therapist, and with parents, is emphasized.

Finally, affective education promotes the youth's ability to become aware of, distinguish among, and appropriately express various emotions. Some youth do not have the vocabulary to properly express their feelings and the therapist can work to normalize some emotions and create a common emotional language. However, other youth may still struggle to distinguish between emotions. Thus, affective education focuses on emotional differentiation. For example, in the *Coping Cat program* for anxiety, the youth and therapist play *Feelings*

Detective in which the youth walks outside of the clinic and looks at other people (“spies”) to label their likely emotions using facial and bodily cues (Kendall & Hedtke, 2006a). Other youth encounter problems when they interpret emotions (e.g., as an all-or-nothing phenomenon) and benefit from the presentation of a dimensional emotional model. For instance, some treatments introduce a “feelings thermometer” in which youth create a visual scale for the target emotional problem (e.g., anxiety, sadness). The scale may be numerical (e.g., 1 to 5), or use metaphors relevant to the child (e.g., least to most favorite color; characters from a comic book ranked least to most scary; the size of sports balls, from golf to basketball). The youth uses the scale to self-monitor mood, and consequently, as a signal to engage in emotion-regulating behavior when they reach a threshold. Finally, affective education involves a review of the three component model of feelings, thoughts, and behaviors (Figure 38.1). Youth gain experience in differentiating the components and in recognizing the interactions among them.

Relaxation

Although not always a part of CBT or BT with youth, relaxation training can be taught to youth to modulate their physiological arousal. Relaxation can be a useful first step in self-regulation. Decreased arousal from relaxation may permit the use of other coping strategies that necessitate higher ordered cognitive resources. Relaxation is part of the treatment for anxiety (Kendall & Hedtke, 2006a, b), depression (Reinecke & Ginsburg, 2008), and c) anger (Lochman *et al.*, 2008). Although some studies have shown beneficial outcomes of relaxation (Deffenbacher *et al.*, 1996; Norton, 2012), other data suggest that relaxation may not be a necessary component of CBT (Rapee, 2000; Hudson, 2005).

Youth are introduced to relaxation with a conversation that contrasts somatic tenseness to feelings of relaxation.

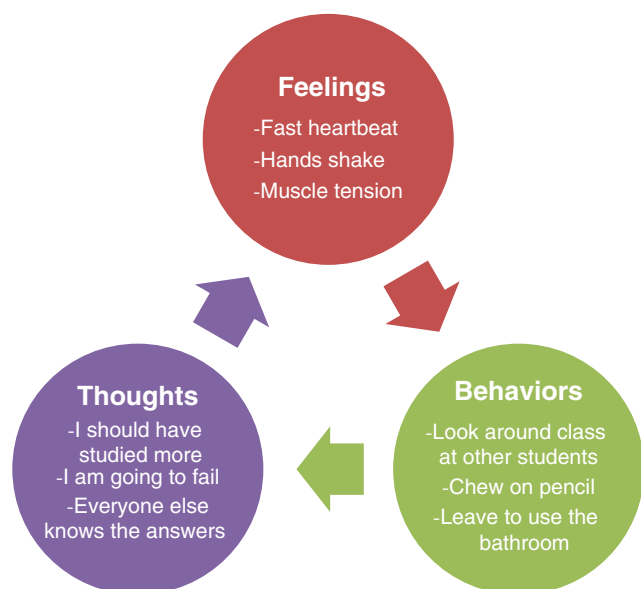

Figure 38.1 Three component model: test anxiety.

The metaphor of cooked versus uncooked spaghetti is one developmentally appropriate way to convey the somatic distinction. Scripts adapted from adults (e.g., Ollendick & Cerny, 1981) are used to teach relaxation techniques. A popular form of relaxation is diaphragmatic breathing, involving deep inhalations into the nose and exhalations out the mouth. Progressive muscle relaxation (PMR) is another example in which youth alternate between tensing and relaxing specific muscle groups. Youth are encouraged to count when tensing (approximately 5 seconds), quickly release the muscle, and contrast the two feelings. Once again, metaphors assist in teaching youth relaxation. For example, in PMR, youth who tighten stomach muscles are encouraged to “fit through a tight fence,” and when clenching their fists they may imagine “squeeze lemons to make lemonade” (Podell *et al.*, 2010). Therapists can make personalized relaxation recordings for youth to practice at home.

Problem-solving

Psychological disorders in youth are often associated with deficits in conceptualizing problems, generating feasible solutions, and putting solutions to action (Lochman & Dodge, 1994; Becker-Weidman *et al.*, 2010). Thus, problem-solving is commonly used in interventions (Shure, 2001; Kazdin, 2003; Kendall & Hedtke, 2006a, b). Problem-solving (D’Zurilla & Goldfried, 1971) teaches youth a systematic way to approach and reduce conflicts, and accordingly, provides a sense of control over the situation. Problem-solving differentiates itself from cognitive restructuring and relaxation: The latter are done to cope with an unavoidable situation, whereas the former is used when the youth has agency over their circumstances (Stark *et al.*, 2010).

Although CBT treatments often provide their own version of problem-solving, the core steps are universal and follow the same order. The steps of problem-solving include: (i) define the problem, (ii) generate as many solutions as possible, (iii) eliminate the unfeasible solutions, (iv) choose the best 1–2 solutions, and (v) implement the chosen solution, evaluate its outcome, and reevaluate as needed (Friedberg *et al.*, 2009). It is often helpful for the therapist to introduce problem solving by attempting to solve a low-threat problem (e.g., “it is time to leave for school but you cannot find your shoes”), and then move to problems related to the youth’s presenting concern. Therapists encourage creative thinking and allow for any suggestion, no matter how outlandish, to be included in the solution generation step (e.g., “wear mommy’s heels to school,” “walk to school on my hands”).

Homework

Homework is a central component of CBT with youth (as well as with adults). According to Hudson and Kendall (2002), homework allows the youth to practice and generalize therapeutic skills in a real-world setting, and provide feedback to the therapist regarding the youth’s comprehension of session material. Although some studies have found that more positive outcomes are associated with homework compliance (Kazantzis *et al.*, 2010; Puleo & Kendall, 2011), some others have not (Clarke

et al., 1992; Hughes & Kendall, 2007). Research shows that homework compliance declines over time (Gaynor *et al.*, 2006).

Homework is used to bridge across sessions. Usually homework is assigned at the end of one session and reviewed at the beginning of the next one. Homework is collaborated with the family and negotiated with the youth. Homework compliance is often rewarded by the therapist (e.g., earning checks that can be exchanged for prizes). Compliance may be defined more in terms of *effort*, rather than *outcome*. Initial homework assignments may focus on monitoring symptoms, whereas later assignments require the youth to practice skills learned in therapy.

Work with parents

Parent's involvement in therapy will vary depending on the age of the youth, presenting problem, and stage in treatment. For example, with very young children therapy is usually centered upon parent management training (Van der Sluis *et al.*, 2012). However, even with older youth parents can participate by being consultants (presenting information about youth), collaborators (assisting in treatment components), or co-clients (using skills to manage their own symptomatology; Kendall, 2012). As therapy progresses, there is a gradual shift or "transfer of control" from therapist to parents in terms of helping the youth manage their stress (Ginsburg *et al.*, 1995).

The content of work with parents will vary by disorder. For example, in the treatment of anxiety disorders parents learn how to help with and even administer exposure tasks. They also are taught to reduce their accommodation of their child's anxious behaviors (e.g., assisting in compulsive rituals, permitting reassurance seeking; Freeman & Marrs Garcia, 2009). Parent management for oppositional youth will involve different skills, such as selective ignoring, praising for prosocial behavior, and learning to deliver effective commands (Barkley, 1997).

Social skills training

Social skills deficits are common across youth disorders. Social skill training is part of CBT when the objective is to "promote skill acquisition, enhance existing skills, and facilitate the generalization of skills across settings and persons" (Bellini & Peters, 2008, p. 858). Social skills training is often conducted in a group format where youth practice newly acquired skills with peers. Typically, a particular skill is introduced by the therapist, the behavior is role-played, the youth practices the skill with another peer or with the therapist, the youth is reinforced and receives corrective feedback, and the youth practices the skill for homework (Foster & Bussman, 2008).

The target social skills vary by presenting concern. For example, internalizing youth may require training that includes speaking up for themselves, giving and receiving compliments, and initiating conversations. On the other hand, externalizing youth may require empathy training (e.g., understanding other's perspective and interpretation of other's facial and bodily cues). Training for this population commonly focuses

on conflict resolution skills, such as: walking away, ignoring, and acceptance and communication of feelings. Social skills programs are particularly popular for treating Autistic youth, and depending on severity, require more intensive training guided by shaping procedures. Basic social skills, including maintaining eye contact and asking the conversation partner questions, are taught. Despite the enthusiasm for social skills training, there is mixed data regarding the efficacy of these programs (Antshel & Barkley, 2008) and uncertainty to the extent that skills generalize to real world situations (Williams White *et al.*, 2007). Research suggests that conducting social skills training in the youth's natural setting may promote more generalizable and enduring effects (Bellini & Peters, 2008).

Contingency management

Contingency management strategies are used for encouragement and learning. Rewards are the cornerstone of contingency management and must be meaningful to the youth to have an effect on behavior (Gosch *et al.*, 2006). It is important to spend time speaking with the youth about potential rewards to be earned for homework completion, practicing therapy skills, and other desired behaviors. Parents of younger children are often instructed to create behavioral charts in which youth receive a point or sticker for a particular behavior. Earned points can be exchanged for various predetermined rewards. Rewards include both tangible (e.g., baseball cards, gift certificates) and nontangible options (e.g., choosing the family movie, cooking with dad). Praise is a key reinforcing agent and is given immediately following a desired behavior. It is important that praise be labeled and specific to the situation (e.g., "I like that you put your clothes in the closet" versus "good job," Eyberg & Bussing, 2010). Ideally, throughout therapy, the youth moves from reinforcement from others to self-reinforcement.

Another side of contingency management is punishment. Punishment is often misunderstood by parents, and consequently overused or misused, potentially contributing to an exacerbation of the problem. Removal of a privilege (e.g., electronic devices and dessert) comes with the opportunity for the youth to earn it back with good behavior. Time-out, used for younger youth with externalizing issues, is considered to be "a temporary removal from reinforcement" and should be short-lasting (roughly 1 minute per 1 year of child).

Modeling and role play

CBT makes use of modeling, a strategy based on observational learning (Bandura, 1977). Stated simply, learning and behavioral change can result from the direct observation of others. Various behaviors, such as approaching a feared stimulus, refining a social skill, or practicing relaxation, can be modeled by the therapist. Therapists model *coping* with stressors (identifying distress, a way to address the distress, and then coping), rather than *mastery* (showing only a solution). Modeling often follows a sequence: The therapist models a desired behavior, the therapist and youth attempt the behavior together, and eventually the youth conducts the behavior independently. In addition to

therapists, teachers, parents, and even other youth can serve as models. For example, in Social Effectiveness Therapy for social phobia, socially competent peers are invited to interact with phobic youth and model socially appropriate behaviors (Beidel *et al.*, 2000).

In “role plays,” the therapist and youth “act out” various real-life situations and rehearse skills. For example, youth with an anger problem can role-play conflict resolution with the therapist who acts as a provocateur. The role play provides information to the therapist about the youth’s proficiency of a skill and areas where it needs refinement. Likewise, role play affords an opportunity for the youth to literally practice the skill and receive feedback. For younger children, role play with puppets can be used. Following a role play, the youth is encouraged to practice their skills outside of session as homework.

Cognitive restructuring

Cognitive restructuring is a phrase often used to refer to changing the way that youth think about situations. It challenges distorted and negative thinking and encourages reasonable self-talk and “coping thoughts.” A first step in cognitive restructuring is developing an awareness of distorted thoughts and their relationship to behavior. In group treatment for adolescent depression, youth are instructed to shout “negative thought” when someone in the group says one (Stark *et al.*, 2007). For homework, youth monitor and record their thoughts. In a next step, youth can become “thinking detectives” or “scientists” and challenge the validity of thoughts with a list of questions (e.g., “Am I sure that it is true,” “Has it ever happened before,” “What’s the worst that can happen”). It is important that youth not merely ask these questions, but answer them. From their answers, they can derive coping thoughts (e.g., “I can do it,” “No one is perfect”). As part of collaboration in CBT, therapists or the youth can write coping thoughts on index cards to create “coping cards” that the youth carry around outside of session.

Flexible adaptations of CBT

Although CBT and BT are typically manual-based, treatments are meant to be applied flexibly to meet the needs of each individual youth. This section reviews ways that CBT can be tailored to the individual.

“Flexibility within fidelity”

Manual-based treatments for childhood psychopathology have gained considerable research support. At the same time, critics have described them as “cookbooks” that dehumanize the therapeutic process, discourage flexibility, and interfere with the therapeutic relationship (discussed in Addis *et al.*, 2006). Advocates of manuals point out that they are to be applied by balancing judicious use with clinical judgment (Kendall & Beidas, 2007).

One suggestion is an emphasis on “empirically supported procedures,” or the overarching principles within manuals

(Abramowitz, 2006). Similarly, Kendall and Beidas (2007) call for “flexibility within fidelity,” an umbrella approach that applies important strategies/components of treatment, while individualizing each to the child. Research could inform the boundaries of flexibility (Kendall & Beidas, 2007), just as research has found that the program has been implemented in RCTs with flexibility (Chu & Kendall, 2009). When considering the boundaries to flexibility, consider: (i) the stated goals of the session, (ii) conceptualizations of the child’s struggles within a CBT perspective, and (iii) action-oriented, rather than passive, treatment (Kendall *et al.*, 2012). As Shirk and colleagues (2012) argued, an increased understanding of core processes will likely increase both an acceptance of manuals by practicing clinicians and the flexible application of manual-based treatments to a variety of youth.

Modular treatments

Difficulties applying treatment manuals in clinical practice have arisen from suggestions that youth in clinical settings may be more complicated than those participating in research trials (Weisz & Gray, 2008). Modular treatment may address these concerns. Modular treatments are considered clinician-friendly and flexible, with the ability to tailor treatment toward each child’s strengths and needs (Chorpita *et al.*, 2004).

One modular CBT for child anxiety disorders, the Building Confidence Program (Wood & McLeod, 2008), has demonstrated initial effectiveness in an individual format for 24 children (ages 5–12) with diagnoses of separation anxiety disorder, social phobia, or generalized anxiety disorder. Specifically, 72% of modular CBT participants were considered treatment responders, compared with 6% of the wait-list control (Chiu *et al.*, 2013). One year following treatment, 71% of children who received modular CBT continued to demonstrate a positive treatment response. Results are considered preliminary based on the sample size and high attrition at follow-up, but nonetheless demonstrate initial promise for the approach in the school setting (Galla *et al.*, 2012).

The Modular Approach to Therapy for Children with Anxiety, Depression, or Conduct Problems (MATCH; Chorpita & Weisz, 2005) has modules that contain elements of other empirically supported programs, the *Coping Cat*, Primary and Secondary Control Enhancement Training, and the Defiant Child therapies. With MATCH, the therapist focuses on the most salient presenting problem, and follows a flow chart that specifies a set of modules to apply. The therapist may then adapt strategies to target comorbidities. MATCH has been found to outperform usual care (Weisz *et al.*, 2012) and a modular treatment (based on prior treatments; Kazdin, 2005) for youth behavior disorders has been found to lead to comparable improvements in both an outpatient clinic and community settings such as the home or school (Kolko *et al.*, 2011). Although the studies suggest initial promise for modular treatments, given their reliance on clinical decision making, some suggest that modular approaches may be less appropriate for novice clinicians (Becker *et al.*, 2012).

Obstacles to treatment

A large disparity has been identified between children in need of mental health services and those who receive treatment (e.g., Collins *et al.*, 2004), such that many children with mental health problems are not receiving adequate treatment. Parents report barriers to children's mental health care, including structure constraints (e.g., cost, convenience, and uncertainty on where to seek care), perceptions of mental health problems (e.g., problems perceived as not serious enough), and perceptions of services (e.g., child refused to go, service was not recommended, and stigma from others). Additionally, parents with life stressors (e.g., unemployment, and divorce) were more likely to perceive barriers to seeking treatment for their child (Owens *et al.*, 2002). Barriers to treatment are key concerns, prompting dissemination and implementation research, discussed in the following sections.

Not all children respond to treatment. When treatment is less than effective, the therapist may wish to contemplate alternate treatment schedules, format, or delivery style. In some cases, an adjunctive treatment (e.g., family therapy) may be indicated. Consider also the possibility of misdiagnosis or poor case conceptualization. Moreover, the therapist may consider relevant process variables, such as giving more time to establish a collaborative relationship with the child. The therapist should be alert to increase child involvement by establishing shared goals. Therapist (e.g., a "preachy" therapist style) and patient characteristics (e.g., impairing behavioral problems) can also be considered.

Internet provided CBT

Given the disjunction between empirically supported treatments and those available in the community, computer-assisted treatments may help facilitate the dissemination of CBT while promoting fidelity to approaches that have empirical support. There are several potential advantages of computer-based CBT programs (Kendall *et al.*, 2011). First, computers reduce the cost of treatment (Olmstead *et al.*, 2010) and they can be available in a variety of settings (e.g., home and school). Computers can provide anonymity and privacy for those hesitant to seek treatment, thereby extending the reach of services. Computers may improve standardization and adherence to key treatment strategies while offering customization for individuals. Data can easily be collected and stored during the use of computer-assisted programs, an effective time and cost saver for clinicians (Khanna *et al.*, 2007).

Research findings have supported several computer-assisted programs for the treatment of child and adolescent psychopathologies; such as *Camp Cope-A-Lot* (CCAL; Kendall & Khanna, 2008) and *Cool Teens* (Cunningham *et al.*, 2007) for anxiety, and SPARX (Merry *et al.*, 2012) and Stressbusters (Abeles *et al.*, 2009) for depression. Ethnically diverse and low-income families have expressed particular interest in online parenting programs (Love *et al.*, 2013). The Triple P Positive Parenting Program (Sanders, 2012) was developed into an

internet-delivered treatment (www.triplep.net) for young children with disruptive behavior disorders and was reported to be superior to an internet help as usual condition (Sanders *et al.*, 2012). Additionally, the Incredible Years parenting program demonstrated initial promise when administered online (Taylor *et al.*, 2008).

Developmental considerations

Although CBT with youth shares similarities with its adult counterpart, there are important differences that reflect developmentally sensitive adaptations. First, there is no such thing as pure "individual therapy" when working with youth. Therapists collaborate with individuals within the child's immediate environment, such as parents and teachers, to develop a therapy plan to assure skills are generalized. Likewise, the therapist negotiates the goals of all involved parties, particularly when working with adolescents.

Unlike adults, youth often do not enter therapy by their own volition. Accordingly, youth may not be motivated to participate in therapy tasks and the therapist may need to spend considerable time fostering incentive in the youth and forging an alliance. With children, rapport is often built by playing games, whereas adolescents may be more engaged by casual conversation regarding topics of their interest. To increase motivation in children, tangible and short-term rewards are used in behavioral contingency systems. Social rewards, such as autonomy to spend time with friends or drive a car, are more appropriate rewards for adolescents. It is also helpful to raise intrinsic motivation of adolescents by discussing how therapy may improve their quality of life and help them achieve their personal goals (e.g., friendship building; getting into college).

Given cognitive and emotional variations in youth, therapy materials are best presented in a way that promotes engagement and comprehension. For younger children the content is presented concretely, with visual aids, handouts (or metaphors) to promote understanding. Therapists are best when they avoid using jargon and over explaining CBT theories. Moreover, it is paramount that therapists provide material interactively and collaboratively. Material can be presented didactically to adolescents, more closely resembling therapy with adults. Likewise adolescents may be able to provide direct feedback when elicited, but children may be reticent because they feel intimidated or struggle to verbally express their thoughts. Using alternative means to receive feedback (e.g., drawings), or simplifying questions so they only require "yes/no" responses can aid the process. As always, it is worth noting that the therapist reassures the youth that their feedback will not get them into trouble.

CBT and BT for intellectual disabilities

As mentioned, cognitive distortions involve a belief about something that is maladaptive, rigid, and/or untrue. By contrast, a deficit reflects a youth underperforming in a particular domain with reference to their culture group and developmental age.

CBT is often used to address disorders that are characterized by distorted thinking (e.g., anxiety disorders and depression), whereas BT is implemented for disorders marked more by deficits (e.g., ADHD, autism, and elimination disorders). Young children, (age 6 and under) and youth with an intellectual disability may have difficulty grasping some CBT content (e.g., not yet ready for perspective taking, meta-cognition) and may be more responsive to BT. Deficits are on a continuum, so cases of high-functioning intellectual disability can respond to CBT with a behavioral emphasis (e.g., more regular reinforcement; Storch *et al.*, 2013). Moreover, the auxiliary visual aids are used to adapt CBT for youth with intellectual deficits or mild to moderate language impairments.

Criticisms of CBT

CBT and BT interventions are not without criticism. Some have argued that the approaches are too narrowly focused on symptom reduction, rather than emphasizing personal growth or the functionality of the family system. Additionally, psychodynamic theorists believe that an emphasis on current symptomatology neglects deeper underlying issues. Finally, although CBT and BT have considerable empirical support, the findings do indicate that a percentage of individuals are treatment “nonresponders” or later relapse.

CBT related therapies

CBT and BT are recommended approaches, but they do not result in remission for all youth participants. Accordingly, alternate therapies, derived from behavioral and/or cognitive theories, have emerged. Mindfulness-Based Cognitive Therapy, Acceptance and Commitment Therapy (ACT) and Dialectical Behavioral Therapy (DBT) are three such therapies.

Mindfulness-based cognitive therapy (MBCT)

Mindfulness, defined as regulating attention toward the present moment while adapting an attitude of curiosity, openness, and acceptance (Bishop *et al.*, 2004), has gained interest as an adjunct to CBT. Grounded in Buddhist traditions, mindfulness includes a variety of techniques that may be applied to youth, such as imagery, meditation, and even yoga. Mindfulness based therapies have yielded moderate effect sizes for adult internalizing disorders, with effects maintained at follow-up (Hofmann *et al.*, 2010). Research with youth is in its nascent stages, but the literature suggests that mindfulness is acceptable and feasible with youth. Preliminary outcomes show some improvement in areas such as anxiety, attention, pain, and academic problems (Burke, 2010). Nonetheless, effect sizes are smaller than in adult samples, youth samples are heterogeneous, and mindfulness has yet to be tested for several types of psychopathology. Moreover, there is a need for more RCTs to determine if the addition of mindfulness adds a significant benefit to CBT or BT.

Acceptance and commitment therapy (ACT)

ACT strives to increase psychological flexibility, defined as being present in the moment and adapting one's behavior according to chosen values (Hayes *et al.*, 2006). Psychological inflexibility is said to be caused by six interrelated problems: cognitive fusion (attachment to one's thoughts), experiential avoidance (attempts to deny or eradicate negative thoughts and feelings), detachment from the present moment (processing past or future events at the expense of present awareness), conceptualized self perspective (fusion with one's self-description), unclear or absent values, and unworkable action (engaging in behaviors incompatible with personal values and counter to desired goals). Each area is targeted in therapy. For example, defusion exercises illustrate that thoughts are transient, can be observed without needing to be controlled, and are nothing more than words. In one exercise, youth repeat a negative word (e.g., ugly) for a minute, after which they are asked to notice that the word sounds funny and has lost much of its meaning. As another example, the therapist may elicit the youth's values by inquiring how they would live their lives in a world without positive or negative consequences for actions. These and other processes are interconnected and clinical judgment determines the area that the therapist initially targets.

ACT is said to contrast with CBT in its philosophical foundations. First, there is a difference in the stated goals: Whereas CBT strives to reduce psychopathology (e.g., emotion regulation) ACT can be said to increase valued living. Although reduction in psychopathology is a concern, ACT theorists argue that it is secondary. Second, CBT questions “distorted” thoughts, seeking a more rational and “adaptive” thinking pattern. ACT rejects the idea of inherently good or bad thoughts and attempts to change one's relationship to one's thoughts. Others have argued that the differences between ACT and CBT are overstated and reflect more differences in philosophy rather than implementation (Arch & Craske, 2008). Both therapies are present-focused, use homework, require active client participation and use behavioral and cognitive strategies to facilitate change.

The literature on ACT with youth is mostly uncontrolled and case studies. Accordingly, conclusions about efficacy are premature (Murrell & Scherbarth, 2011). One study of youth with chronic pain found that ACT outperformed usual treatment at posttreatment and 6.5 month follow-up on pain intensity and interference (Wicksell *et al.*, 2009). Systematic research is needed regarding ACT with youth.

Dialectical behavior therapy

Dialectical Behavior Therapy (DBT) is akin to CBT (e.g., problem solving, behavioral strategies, skills training, and practice), but differs a bit in its delivery and philosophy. DBT was developed for individuals with chronic suicidality (Linehan, 1993a, b) but has been applied to adolescents with severe behavioral and emotional dysregulation. DBT theory combines elements of Zen, behavioral science, and dialectical philosophy. In brief, DBT postulates a worldview through which

opposing forces exist simultaneously and can lead to conflict. As a result, dialectical change occurs when opposing forces are resolved. The DBT therapist strives to help patients by reducing maladaptive behavior, promoting positive behavior, and helping to “build a life worth living” by providing a validating, supportive environment (MacPherson *et al.*, 2013).

DBT consists of stages: (i) pretreatment, including orientation and commitment of the patient to goals, (ii) reduction of life-threatening behavior and behavior that interferes with therapy and quality of life, (iii) reduction of posttraumatic distress and increase of normative emotional experiences, (iv) working toward achieving typical levels of happiness through goal achievement and increasing self-respect, and (v) working toward achieving lasting contentment by resolving sense of incompleteness. Therapy includes individual sessions, group skills training and telephone coaching for the participant, and consultative/supportive sessions for the therapist (MacPherson *et al.*, 2013) and is intended to be provided flexibly. A DBT manual for adolescents (Miller *et al.*, 2007) was adapted from the adult version and research suggests that DBT has some support for the treatment of adolescent borderline personality disorder, bipolar disorder, suicidality, oppositional defiant disorder, and eating disorders (Macpherson *et al.*, 2013).

Future directions

There is good news! Treatments for youth psychopathologies described here have been developed, evaluated, and often determined to be efficacious (Kendall, 2012). Given this status, the field needs to focus on transporting these treatments into use in everyday practice (Kendall & Beidas, 2007). Related to this, dissemination and implementation (DI) is rapidly growing. An American Psychiatric Association (APA) Task Force issued a policy statement calling for effective mental health care for youth across settings and clinicians that is “based on scientific knowledge and integrated with clinical experience in the context of patient characteristics, culture, and preferences” (APA Task Force on Evidence-Based Practice for Children and Adolescents, 2008, p. 6). Despite this recognition and related efforts, CBT remains underutilized in the community (Shafran *et al.*, 2009). In a national survey, 47% of therapists reported never having used a treatment manual (Addis & Krasnow, 2000). ESTs can call for extensive training and ongoing consultation of clinicians (Edmunds *et al.*, 2013), which can be costly. However, such efforts are likely warranted to ensure fidelity to the essential “ingredients” of ESTs particularly in the context of community clinics. With this in mind, emerging efforts to disseminate treatment for a variety of psychological disorders exhibit promise (Spence & Shortt, 2007; Loeb *et al.*, 2007; Southam-Gerow *et al.*, 2010).

Ethnic minorities have been under represented in ESTs (Silverman *et al.*, 2008) and some studies suggest that minority status may be associated with poorer outcomes (Chronis *et al.*, 2004), whereas others suggest comparable outcomes across ethnicities

(Pina *et al.*, 2003). Future research should consider the development of culturally sensitive and culturally adaptive therapies. Will outcomes be superior if treatments are modified to integrate differing values (e.g., parenting practices and religious preferences)? How does a family’s level of acculturation influence treatment compliance, completion, and outcome?

A next step toward personalizing treatment is to examine and better understand the mechanisms of change. In their review, Shirk and colleagues (2012) determined that although research on therapy process in CBT for youth has grown, unanswered questions remain. They argued that we need research to understand the essential mechanisms of change. The results of such work may in turn, increase the overall efficacy of treatments, inform the training of future therapists, and increase the cost-effectiveness of therapy by streamlining manuals to the essential elements (Chu & Harrison, 2007). The identification of treatment mediators represents a worthy effort to identify variables that account for therapeutic change. Research suggests potential treatment mediators, such as parenting practices within disruptive behavior disorders (Beauchaine *et al.*, 2005) and cognitive processes in anxiety (Kendall & Treadwell, 2007) and depression (Chu & Harrison, 2007).

Finally, a relatively new area in the field of child and adolescent psychopathology is the development and testing of transdiagnostic treatments. Given that comorbidity in youth psychopathology is the rule, rather than the exception, transdiagnostic therapies can be tailored to address the complex needs of youth with comorbid diagnoses. Such therapies may be more efficient and cost-effective, reduce attrition, and promote dissemination (Rohde, 2012). Recent efforts to test transdiagnostic treatments for youth mood and anxiety disorders offer initial promise (e.g., Chu *et al.* 2009; Bilek & Ehrenreich-May, 2012).

CHAPTER 39

Family interventions

Ivan Eisler¹ and Judith Lask²

¹Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

²University of Exeter, Exeter, UK

There is a wide acceptance of the role of the family environment in contributing to the emotional and psychological well being of a child. When a child presents with mental health difficulties professionals need to form an effective working relationship with those who care for the child. Work with the family can take many forms and will be based to a considerable degree on our particular understanding of the role that family factors play in relation to the development, maintenance, and above all the resolution of presenting problems.

We will discuss why clinicians need to be cautious in attempting to translate research data on family factors into putative etiological explanations at the level of the individual child and the implications this has for how we engage families in treatment. The chapter will examine different approaches for working with families and the factors which may indicate whether this is an appropriate approach.

Family interventions in the broader context of other psychological treatments

Family therapy, like other psychotherapies, has evolved over several decades and today includes a broad range of ideas and techniques that are often described as representing discrete theoretical models (e.g., structural, strategic, Milan systemic, and narrative—see Carr, 2012 for an overview). In practice, the conceptual ideas and techniques associated with each of these tend to be adopted quite widely and most family therapists integrate ideas from different approaches in their work as single theoretical models often do not provide sufficient conceptual breadth or choice of interventions to address the wide range of difficulties presented to clinicians. The boundaries between systemic family therapy and other therapeutic approaches are also frequently blurred with many overlaps.

The role of the family therapist in the multidisciplinary team

Most clinicians working with children and adolescents will include families in their work. This is sometimes referred to as “family work” or “family interventions” to distinguish it from “family therapy,” although the distinction is somewhat artificial and usually refers more to the level of training of the clinician rather than necessarily to a different approach. Family therapists by virtue of their training will have developed specialist skills in working with families, may take on more complex work and should be more able to adapt interventions to suit the needs of individual families. However, where there is an indication for family interventions, the same principles should apply whether the specialist family therapist or the nonspecialist carries out the work. The role of the family therapist within the multidisciplinary team is of course much wider than just seeing families. They will be able to identify when a family approach is likely to be helpful and the different styles of work that might be best suited for the specific problem or a particular family. Moreover, the family therapist can also provide support and supervision for other team members working with families.

There is a wide continuum of ways that the family may be involved in treatment. This includes taking part in assessments, providing a supportive role in relation to other, more child focused interventions such as cognitive behavioral therapy (CBT), through the family being the main vehicle of engagement for a reluctant child or adolescent, to family therapy being the main focus of treatment. It is helpful for all clinicians involved with children to have basic skills in engaging and communicating with families and for teams to have sufficient expertise to offer specific, family-focused interventions as well as clinicians trained to offer more flexible systemic family treatments for more complex problems or more difficult family situations.

Theoretical considerations informing work with families

The family context of individual problems and the broader social environment

Observing the child in the presence of his/her family will provide a rich source of information that contextualizes and often provides new meaning to the child's behaviors. It also provides insights about the strengths and resources of the family and the community in which they belong as well as constraints that may come from lack of time, relationship difficulties, other family stressors, and factors such as social deprivation or the threat of crime or racism. It is important to consider the wider contexts surrounding the family, including culture, the diversity of family life across cultures, and the considerable change that families have undergone in most societies, as these will affect basic values and beliefs around family relationships. The notion of what family life means in terms of the nature of family relationships, the expectations of the way in which families change over time or the roles of different family members varies hugely. Children may grow up in foster and adoptive families or a succession of different families or may be part of more than one family constellation following marriage break up. Single-parent families, same-sex parent partnerships, and friendship networks provide different forms of family life. While much of this may appear self-evident, it is crucial to be open to the different experiences and expectations that families bring with them. Moreover, we have to be aware that as professionals our own personal and cultural perspectives will inevitably color our observations and assessments.

Exploring the family's social and cultural contexts will also provide information on stresses (e.g., specific social expectations in the community) and resources such as sources of networking and support (Falicov, 1995). An evaluation of the role of professionals in the referral process and the history and relationship of the family with other helping systems is important, particularly where there has been multiagency involvement, which may itself have become disabling for the family (Asen, 2002).

The family as a system

Family Systems Theory, the conceptual framework for much of the thinking about working with families, has evolved considerably over the years. The original notion of the family as a system described a number of features such as the recursive nature of relationships, the multilevel nature of communication (Bateson, 1972), the development of recognizable patterns of interaction, the role of relationships and beliefs, and the allocation of family roles (Carr, 2012). Minuchin (1974) described aspects of family organization such as boundaries and hierarchy and placed a particular emphasis on promoting an effective parental alliance and maintaining boundaries in a way that fostered the development of a secure sense of identity with appropriate individuation. In the 1980s and early 1990s, a major theoretical shift in systems theory emphasized the interplay between being an observer of a system and being part of the same system (Hoffman, 1985).

This has had key implications for understanding the active role that individuals have in construing reality, the limitations to the objectivity of observations (Hoffman, 1990) and the role of language, culture, history, and other social discourses in influencing our perceptions of the world around us (Gergen, 1999). This has shaped the practice of family therapy, moving it away from the notion of "treating families" to "treatment in collaboration with families"; in other words seeing families first and foremost as a resource to help their child overcome problems rather than the origin or source of dysfunction.

The role of the family in the development and maintenance of psychopathology

The family environment is the main social context that shapes and modifies the individual, biologically determined predispositions of the child and is also the context where the main developmental psychological needs should be met. The family context provides meaning to behaviors and is where individuals learn and practice how to manage emotions and feelings and manage the idiosyncrasies of their temperament and personality. The research literature highlighting the role of the family is huge and cannot be reviewed here in detail but the factors that would need to be considered include a range of prenatal factors such as being an unwanted child (Kubička *et al.*, 2002) or maternal stress (Huizink *et al.*, 2002), the consequences of growing up in an environment characterized by negative emotion, harsh parenting, high levels of discord or hostility (Waller *et al.*, 2012), or the impact of neglect (Rutter & O'Connor, 2004). Of course, as many have pointed out, such negative family factors have to be considered alongside those factors that may have a protective role or promote resilience (Rutter, 2006; Bowes *et al.*, 2010).

When considering family factors in relation to the development of specific problems, however, considerable caution is needed. Explanatory family models of particular disorders have often been proposed with limited empirical support other than clinical observations. Where associations are found between family factors and a disorder, these may be risk factors (often nonspecific) or maintaining factors rather than causal etiological factors. Even where there is robust evidence for particular family factors increasing the risk of a disorder(s), their relative contribution is often small. A good example is the evidence concerning parenting styles. These have been consistently shown to be associated with a range of child and adolescent difficulties but they account for less than 10% of the variance (McLeod *et al.*, 2007a, b; Buschgens *et al.*, 2010).

The dynamic relationship between family, child, and problem is complex and clinicians should desist from drawing simplistic conclusions and in particular making causal etiological inferences based on here-and-now observations. What we observe when assessing a family is the outcome of a complex interaction over time between the effect of the family environment, personality, and temperamental characteristics of the child, the impact of the developing disorder on the family, and resilience factors as well as mediating genetic factors (Kraemer *et al.*, 2001; Plomin &

Daniels, 2011; Rutter, 2013). There is also evidence that even the most adverse factors do not have uniform effects (O'Connor *et al.*, 2000) and what applies at a group level may not translate to the individual child.

It is important that clinicians hold the empirical evidence about the role of family factors as part of a broad background without making assumptions too readily about their direct relevance to the current family. This is partly to avoid the pitfall of drawing unwarranted causal inferences but also helps to engage families in positive ways instead of adding to their sense of failure and self-blame.

Impact of individual problems on family life

When one member of a family begins to develop a problem, it affects other members and the family as a whole. Some effects may be readily apparent such as aggression toward siblings from a young person with attention deficit hyperactivity disorder (ADHD), some may be less obvious, for example, “well” siblings receiving less attention from parents (Areemit *et al.*, 2010). The stress of dealing with difficulties may put a strain on the parents’ relationship or the relationships with wider family. The way the family adapts to the impact of illness tends to be gradual and will often start through the activation of protective and supportive processes in the family but can in time become part of what reinforces or maintains the problem. For example, what may start as supportive reassurance of an anxious and perhaps somewhat perfectionist child may with hindsight turn out to be the start of a process of parents being drawn into the emerging rituals of a developing obsessive-compulsive disorder (OCD) (Amir *et al.*, 2000). Useful models for understanding the process through which the family accommodates to the child’s problem can be found in the studies of the impact on the family of enduring physical illness and disability (Cole & Reiss, 2013) as well as psychiatric illness (Muhlbaier, 2002).

The way families respond to a developing illness depends both on family factors and the specific problems that the illness brings but there is a general tendency for the problem to magnify certain aspects of the family’s dynamics and narrow the range of their adaptive behaviors (Eisler, 2005). As the illness increasingly takes a central role in family life, what may be normal variations in family functioning become more pronounced and take on new meanings. Concern may begin to feel like overprotection and intrusiveness, while attempts to promote independence may feel like lack of care. Much of what we observe in families we meet as clinicians can be understood, at least in part, as an outcome of the process of family adjustment to the problem and should not be too readily labeled as dysfunctional.

The family life cycle

The Family Life Cycle model (McGoldrick *et al.*, 2010) provides a “developmental lens” for understanding the way the family as a system evolves over time and how families adjust to different cultural and social expectations and pressures. Families need to provide stability but also have to be able to change in order to

adapt to new circumstances and the developmental demands of family members. For instance, the child’s need for dependence and attachment requires a degree of stability and constancy in the family but, as the child develops, the family must find ways of meeting his or her needs for independence and separation too. As the family evolves through the family life cycle stages, it needs to be able to adapt and change its habitual style of functioning. These stages can be complicated by unexpected events such as illness, death, family separation, unemployment, or migration, and the combined stress can contribute to the development of problems. There is evidence that at these transitional times there is an increased vulnerability and increased psychological morbidity (Hetherington, 1989; Lueck & Wilson, 2011). The way the family responds to an emerging problem is a crucial factor in determining the extent of individual vulnerability to such pressures (Walsh, 2006). It is useful to explore with families how they managed key transitions and significant life events, the impact these may have had on family life and family relationships and the resources and strengths that helped them to manage these in the past.

A conceptual framework for working with families

Creating a safe context for working together toward change

Part of the effectiveness of family therapy will be the skill of the therapist to develop and maintain the engagement and motivation of family members. In many ways, this is not different from engagement in any other kind of therapy and requires the development of an emotional connection with the family and an agreement on the tasks and goals of therapy (Bordin, 1979) but additional factors come into play when working with families with a key aspect of alliance being the development of a shared purpose of treatment by the whole family (Escudero *et al.*, 2008). It is important to overtly recognize that there may be multiple viewpoints and ensure that everyone is engaged and heard. Therapists have to balance their position as experts (often a key element of creating a sense of safety in the early stages of treatment) with the need to ensure as collaborative an atmosphere as possible (Mason, 2005) while also respecting individual, social, and cultural differences in expectations of professionals.

Even very young children can be effectively included in family interviews, provided this is carried out in an age-appropriate way. Engaging a child effectively is often reassuring for parents, who may be concerned whether bringing the child to a psychiatric setting is the right thing to do. The choice of language in talking to parents about their child’s problems is also important as it may be difficult for the child to understand what is being said. Often it is better to ask the parents to explain things to the child, as this may be less threatening for the child, and reinforces the sense that the parents are the experts in their own child.

Young people may not be too keen to take part in discussions at first, particularly if they feel blamed for the problems. Making it clear that it is OK to sit and listen is often important to avoid making the child or adolescent feel that they are being put on the spot and can help avoid unhelpful battles. When the pressure on them to join in is removed, they will often join themselves. The advantage of a family interview is that even a reluctant or unwilling participant can be included in an interview through indirect means, for example, making nonverbal contact, making observations or comments that include the young person and so on. With young children, this may include joining with a child in creative play, talking about a drawing he or she has made or using puppets or story making (Wilson, 1998).

Frameworks for change

In recent years, there has been a growing move toward integrating different approaches, both from within the family therapy field and outside it (Norcross & Goldfried, 2005). As Fraenkel and Pinsof (2001) point out clinicians either include techniques or ideas from other approaches without modifying their own conceptual framework or they integrate them at a theoretical level making it possible for different conceptualizations of the therapy process to be used and applied depending on the nature of the problem, stage of treatment, or difficulties encountered in treatment.

In this section, we outline a set of conceptual frameworks that provide an integrative way of thinking about different interventions and the process of change. They draw on earlier models of family therapy and the specific processes that these focus on but recognize that change happens on a number of levels. These frameworks are, of course, not mutually exclusive and most interventions will include elements of each.

Maintenance framework

Much of the early theory informing family therapy was concerned with the idea of the family as a self-regulating social system, the way in which family interactions and family structures maintain problems and two influential strands of family therapy (Structural and Behavioral) have drawn heavily on these ideas. The notion of maintenance does not make any assumptions about the origin of difficulties but postulates that families become organized around problems in a way that may contribute to their maintenance either by directly reinforcing problems or by disrupting adaptive or change processes.

The here-and-now focus of structural and behavioral interventions is of particular relevance for the understanding and intervening in possible maintenance mechanisms. Enquiring about the usual way in which the family operates, family rules, family roles, and boundaries and how this has changed around the problem will give insight to family strengths as well as potential areas of difficulties. When discussing patterns that may be connected to a specific problem, the clinician has an important role to help frame or ask questions that evoke non-blaming descriptions. The aim here is partly to avoid reinforcing

disabling feelings of guilt and blame and partly to set a context which encourages family members to be self-reflective and consider their own part in the pattern and what they can do to bring about change.

From the perspective of a maintenance framework, change can take place through interventions that are aimed at directly changing patterns or sequences of behaviors including actively intervening in the process of discussion with encouraging language, highlighting success, interrupting repetitive or escalating patterns, or exploring opportunities for the therapist to help the family to "do it differently." Parents may be encouraged in the session to have more constructive conversations about parenting or to tell their child what they want him to do rather than just complain about what he does do. Similarly, the adolescent might be asked to reflect what he would do if he thought that the parents had started listening more. While generally these are interventions that require the therapist to take an active and often quite directive role, it is also important to invite self-reflection by the family on their patterns and to assess the impact of following a different pattern.

Influencing framework

All psychotherapies are concerned with bringing about change but what characterizes this framework and the approaches that have this as their key focus is the interest in how change is brought about and the purposeful role therapists have in bringing about change. The two groups of systemic therapies that are most clearly identified by this framework are Strategic therapies (Haley, 1963) and Brief therapies (Weakland *et al.*, 1974) the latter eventually developing into what is now known as Solution-focused therapy (de Shazer, 1985). The focus was on the interactive process that interfered with change, rather than the processes that maintained problems and the role of the therapist was to intervene strategically to interrupt the processes that blocked change.

Many of the minutiae of the therapy process, such as the choice and sequencing of interventions, how and when therapists use their expert knowledge, or when on the other hand they emphasize the limits of their expertise and invite families to look for their own solutions, can be understood as part of this framework. While all interventions can be considered from the perspective of an influencing framework, clinicians should consider in particular how they use interventions that aim to change behaviors or perceptions in specific ways and the way they use, directly or indirectly, their authority as therapists to achieve this. In doing this, they need to consider the broader context, for example, the choice of whether to have a conversation with the adolescent or with one of the parents, how different family members might respond to different questions as opposed to being "participant listeners," the effect on the therapeutic relationship and so on. The importance of considering this framework is that it overtly acknowledges the power of the therapist (positive as well as potentially negative) and requires therapists to be aware of and reflect carefully on their own motivation, their position

in the system, on the impact they are having and the effect of their interventions on their relationship with the family. For instance, there is evidence from both individual psychotherapy research (Castonguay *et al.*, 2010) and family therapy research (Escudero *et al.*, 2012; Lambert *et al.*, 2012) that when there is a disruption to the therapeutic alliance, continuing with interventions that are usually effective can be counterproductive and may undermine treatment and in some cases cause harm.

The framework is also useful when considering tasks outside of the direct “therapy setting.” For instance when writing letters to referrers which will be copied to the family, clinicians should always reflect on how the letter will be perceived by family members (children as well as parents). Such letters are not just a means of conveying information about an assessment, they also provide an opportunity to frame such information in ways that can be helpful or less helpful for the family and influence shared understanding by the family.

Frameworks focusing on changes in belief and meaning

An important idea that underpins all family therapy approaches is that problems are embedded and shaped by their social context and to a lesser extent help to shape the context. If we try to understand the interpersonal nature of problems, it is almost inevitable that we become concerned with language, beliefs, cognitions, and narratives because these are central to understanding the process of social interaction and the shaping of behavior through the meaning attached to it.

Several influential therapy approaches have placed language and narratives center stage of treatment, most notably Narrative Therapy (White, 2005) and the Collaborative Language approaches (Anderson & Goolishian, 1988). These emphasize the role of language and narratives as the vehicle through which people acquire their definitions of self. Individual problems are understood to be, at least in part, the result of the filtering of experiences through narratives that people have about themselves. From the perspective of this framework, change occurs through the emergence of new narratives, which alter the understanding of self as well of relationships with others. The skill of the therapist is to focus attention on small aspects of neglected or unnoticed narratives, which then may acquire a greater salience for the individual or the family. A negative, constraining narrative may thus be replaced by a more positively supported alternative. Part of the work is to identify “dominant stories” and help to identify exceptions or unique outcomes to counter the power of the (usually unhelpful) story. For example, a mother may have a firm idea that she will not be able to stand up to her children and may therefore withdraw or become over-disciplinarian. Uncovering examples of her effectiveness and skill as a parent or times she has stood up for herself in everyday life may help her change her view of herself and enable her to take another approach.

Increasingly, therapeutic work with families also includes explorations of the role that emotions and feelings have as

specific organizers of beliefs, behaviors, and relationships. This may include exploration of attachment relationships, which may have become important components in problem behaviors, arousing overwhelming emotions that can direct individuals toward self-protective behaviors rather than ones that take into account others in the situation (Vetere & Dallos, 2008).

Practical issues and techniques of family interventions

Whom to see and when

Although it is always useful to witness the whole family interacting together, conjoint interviews also have their limitations in both the assessment and treatment phases. During assessment, there may be indications that some individuals do not have an effective voice in the family group or the presence of the whole family may seriously inhibit some aspect of discussion. An adolescent may not want parents to know about drug use or there may be concern that a child has been abused and may be unwilling to talk about this in front of parents. Similarly, there may be issues that parents may not wish to discuss with the child present (e.g., when parents of a child with disability may not be able to share negative feelings in front of the child). For these reasons, it is generally useful to make at least some separate sessions a routine part of practice even when family therapy is indicated as the main mode of treatment.

There are several other considerations that should be taken into account when deciding on individual or conjoint sessions. For instance, the therapist might decide that it is age-appropriate to see an adolescent on their own, particularly if they express a wish for this. The therapist should consider (and enquire about) to what extent this is determined by a wish to avoid talking about a painful or upsetting issue, which may not necessarily be a helpful thing to do. Some topics may appear difficult to address in a conjoint meeting although the discomfort may at times be largely to do with the clinician’s own uncertainty about how or whether to raise the issue. Asking questions about what is acceptable or usual in the particular family will tell the clinician what can or cannot be easily talked about and may open up the topic for discussion. Questions such as “If your parents thought you were smoking dope, what would they do?” or “Some teenagers are very up-front about what they get up to, others keep things closer to their chest—what is your son like?” may quickly lead to frank and open conversations. More importantly, this kind of discussion will clarify what the actual boundaries in the family are rather than being assumed by the therapist.

The family interview is an important component in a comprehensive assessment. It provides the clinician with an opportunity to observe the family in direct interaction, to assess patterns of relationships, the emotional climate of the family and a chance to consider how the family is organized around the child’s problem. Interviewing the family for purposes of assessment is a good starting point for making an effective treatment alliance with

the family. Hearing the concerns of family members and their hopes for the future is as important as gathering information and making an assessment of the problem and can determine the most effective ways of helping the family to promote change.

In families where there is much hostility, criticism or open conflict, conjoint meetings may not always be helpful, particularly if the hostility or conflict simply escalates in sessions. There is evidence that families with high parental scores on criticism are more likely to drop out of treatment (Szmukler *et al.*, 1985) and outcomes may be better if parents and the young person are seen separately (Eisler *et al.*, 2000, 2007).

The context of family sessions

The context in which family sessions take place will have significant impact. If it is in the clinic, it may appear strange and inhibiting especially to small children but on the other hand may appear “neutral and safe.” In some settings, such as inpatient units, it may be necessary to more clearly delineate boundaries for other staff and ensure that there is a quiet space for interviews and that there are no other competing demands. Family therapy in an inpatient context is of necessity different in that the child or adolescent is not with the family between sessions, and day-to-day responsibility does not rest with parents. This limits the possibility of the family working on changing ways of dealing with the child’s problems and can reinforce the sense that it is the hospital’s responsibility to “fix the child.” The hospital context, on the other hand, can provide a sense that the child is in a safe place and may allow addressing upsetting or painful issues that at other times would feel too risky and would be avoided. Home-based interviews can be very useful in learning more about the family and may make it easier to engage some families. However, it may be difficult to manage interruptions and it is easier for a family member to leave the room if they become upset. Moreover, it may be more difficult for a session to end and some of the feelings may remain for longer. If the whole treatment takes place in the family home, families may also feel that they have less control how long treatment continues for and how it should end. The setting is important and the therapist must consider how best to make the most of the advantages and guard as far as possible against the disadvantages.

Specific interview and intervention techniques

It is beyond the scope of this chapter to cover in depth the variety of techniques that have been developed for working with families (Dallos & Draper, 2005; Carr, 2012) but questioning techniques play a central role. They not only gather useful information about patterns of interaction, family differences, and the connections between relationships, behavior, beliefs, and emotions, they also invite family members to reflect and become observers of themselves. Questions can also be used to invite action or they may include embedded suggestions—for example, a mother may be asked “What would happen if you were able to hide your worry when your daughter got depressed?” to encourage her to think about protecting her

daughter. Tomm (1987a, b, 1988) provides a useful overview of different kinds of “circular questioning” which provide a basis for describing the problem in a more contextual way and also allow for alternative descriptions to be heard.

One way of organizing the use of circular questions is to connect them to a systemic hypothesis. The therapist links information about the family to form a hypothesis about the family and their relationship to the presenting problem. This hypothesis is tested through circular questions and revised in the light of feedback until an idea is arrived at that fits well enough with the family to provide useful new information for them. Relative influence questions are specifically linked with the technique of externalizing the problem and explore the influence the problem has had on the person(s) and, more importantly, the influence the person has had on the problem. Through the process (e.g., of exploring how the family has helped a young child with fears or anxiety), it may be possible to establish exceptions or unique outcomes when there has been some control over the problem and how these can be developed further.

There are numerous techniques for intervening in the process of family interaction (Minuchin & Fishman, 1981) including blocking repetitive patterns that reinforce unwanted behaviors, highlighting constructive behaviors such as positive parenting, or setting rules to prevent repetitive escalation of arguments. Interventions may be fairly unobtrusive nonverbal ones (fixing the gaze of the person who is speaking, making it more difficult for others to interrupt) or more overt, even dramatic gestures (“Why don’t you go and sit next to your dad and try to work out a compromise, without getting mum to help?”) and may include specific suggestions or homework tasks. Alternatively, the therapist may comment in a way that draws attention to what is happening.

Genograms, family drawings, and other techniques

Genograms have great value in family work and are used to map out the family and family relationships, to explore beliefs, traditions and identify strengths, resources, and areas of resilience (Gil *et al.*, 2008). It is useful to include family members over three generations (to gather information on transgenerational influences), their occupations, gender, and dates of events such as marriage, relational breakdown and death, and a pictorial representation of positive or negative relationships. While gathering information is an important part of a genogram, far more important is that it is an opportunity for the family to reflect on how they view themselves, their values and sense of identity and engendering a sense of shared history. It is also an opportunity to move beyond problem talk and to identify strengths, evidence of courage and resilience and family resources that can be used to overcome problems. Family members who have been less central can also be more actively involved in completing a genogram. As with all techniques, care must be taken to be aware when sad or upsetting things are revealed. It may be particularly difficult for those who have lost important family members or who are

alone or whose families are not known. The culture of the family should be taken into account throughout all work with families but is of particular importance when doing genograms as it provides an opportunity to talk about family beliefs, family history and culture, and the way that these have shaped the way of dealing with different problems.

A range of other visual and drawing tasks can be used with families, particularly when engaging children. Some more common ones are maps of relationships, which place the child in the center and place people at different distances on the map. This will sometimes reveal important people outside of the family. Simple drawings of the family or a family activity can provide important information and a focus for discussion. Progress in overcoming difficulties can be set out in a visual way. One example is an image of a mountain with “success” at the top. The child’s “team” can be listed and hopefully this will include family members and the way they can help.

Contraindications for family interventions and/or indications to proceed with special care

Criticism, family conflict, hostility, and violence

Many family sessions will include some negative comments and hostile attitudes, which will hopefully change as family members become more confident in the setting. However, if this persists, it is important to make a judgment about the level of harm it may do to the more vulnerable members. If the hostility is between parents, it may be important to have a separate session to discuss whether their relationship issues are getting in the way of their ability to work together as parents in dealing with the child’s problem. If criticism is difficult to contain, parallel sessions with parents and the young person may be more helpful at least in early in treatment.

If there are indications that there is violence in the family (e.g., aggressive atmosphere in the session or allusions to violent behavior), it is important to consider the possibility of how this is best explored in a safe way to minimize the risk of violence escalating after the session (Goldner *et al.*, 1990). In such situations, family sessions may be problematic but the information gained from an initial family assessment can still be useful in deciding about future interventions. If parents share concerns about what is happening and want to make changes, work with the family alongside other safeguarding measures may be very useful. If therapy with the whole family does proceed, it can only be undertaken with an agreement to stop the violence and a clear safety plan for the person(s) at risk.

Abuse and neglect

Abuse or neglect may not always be directly evident in sessions (e.g., there may be no overt hostility) but there may be other indications of abuse and neglect. From the start, it is important to be clear that if concerns about safety arise it will be necessary

to act on those (usually with the knowledge of the parents). An assessment must be made about levels of concern and safeguarding steps taken if there is fear of ongoing physical, sexual, or emotional abuse. While work with the family can be helpful, work with the whole family requires an acknowledgement of the abuse and an acceptance of responsibility (Barratt, 2012). The safety and protection of children has to always take precedence over other therapeutic needs.

Disorganized and poorly functioning families

It is sometimes assumed that family dysfunction should be the main indication for family therapy. In fact, the opposite is the case. Several studies have shown (Hampson & Beavers, 1996a; Barrett *et al.*, 2004) that family factors moderate the effect of family therapy, with poorly functioning families gaining less benefit. This should not be taken to mean that more dysfunction simply leads to poor outcome, as there is evidence that these effects might be specific to particular types of family intervention. For instance, collaborative treatment approaches (often favored by therapists) are less effective with disorganized families (Hampson & Beavers, 1996b), who tend to respond better to more directive and less open styles whereas the opposite is true of more balanced type families. Evidence of disorganization or poor family functioning does not mean that family therapy is contraindicated, rather that we need to proceed cautiously and that a higher degree of expertise or team support is needed to ensure that family interventions are both safe and effective.

Research evidence informing family therapy practice

The evidence showing the efficacy of family interventions is increasingly strong with a growing number of well designed, appropriately powered multisite studies appearing in recent years. A number of reviews provide both a general overview of the empirical evidence for the field as a whole (Kaslow *et al.*, 2012; Sprenkle, 2012; Retzlaff *et al.*, 2013; Sydow *et al.*, 2013) as well as for problem specific areas such as alcohol and drug abuse (Waldron & Turner, 2008; Baldwin *et al.*, 2012; Rowe, 2012), conduct disorder and delinquency (Baldwin *et al.*, 2012; Henggeler & Sheidow, 2012), eating disorders (Downs & Blow, 2013; Couturier *et al.*, 2013), anxiety disorders (Breinholst *et al.*, 2012; Simpson *et al.*, 2012), or mood disorders (Carr, 2008; Cosgrove *et al.*, 2013).

General reviews show family therapy to be effective when compared to no treatment or wait list controls (with an average effect size of 0.65—Shadish & Baldwin, 2003). With most problems, the differences between family therapy and other active treatments are relatively small but with some there is consistent evidence of family therapy leading to better outcomes. This is particularly the case for behavior problems and youth offending (Henggeler & Sheidow, 2012; Sydow *et al.*, 2013) and substance misuse (Baldwin *et al.*, 2012; Tanner-Smith *et al.*, 2013) where the evidence from around 30 RCTs provides clear support

for the use of family therapy both in terms of outcome (with small but consistent between-treatment effect sizes of around 0.26—Baldwin *et al.*, 2012; Tanner-Smith *et al.*, 2013) but also because family therapy appears to be more effective in engaging and maintaining young people in treatment than individual therapy (Stanton, 2004).

Similarly, there is now compelling evidence for family therapy in the treatment of eating disorders (Downs & Blow, 2013; Couturier *et al.*, 2013) with recent larger studies confirming its superiority in the treatment of anorexia nervosa in comparison with an adolescent-focused individual therapy (Lock *et al.*, 2010) as well as its role in the treatment of bulimia nervosa (Le Grange *et al.*, 2007; Schmidt *et al.*, 2007).

For other problems such as anxiety disorders (including OCD), depression, or bipolar disorder, there is evidence that family interventions are effective but the comparison with other treatments is less straightforward. In anxiety disorders, most of the family intervention research has compared different versions of individual or family-based CBT. Generally, individual and family-based CBT tend to have similar outcomes, but the overall picture is more complex. Some studies have shown that where the parents themselves are anxious, including a family component in treatment may increase effectiveness (Kendall *et al.*, 2008) but this is not the case in other studies (Bodden *et al.*, 2008). There are also data suggesting that even when there is no difference between changes in anxiety symptoms, the family intervention leads to greater changes in general functioning both at the individual and family level (Khanna & Kendall, 2009) and some studies also indicate a better longer term maintenance of posttreatment gains (Barrett *et al.*, 2001; Cobham *et al.*, 2010). In mood disorders, a wider range of family interventions have been evaluated. These have included CBT with a family component where the findings are similar to anxiety disorders, that is, they are effective in comparison with a control but are similar to individual CBT, although again there is some indication of greater change in family relationships (Stark *et al.*, 2012). Two groups have evaluated systemic family therapy for depression in children and adolescents and shown them to be effective in comparison with control (Diamond *et al.*, 2002, 2009) and comparable to psychodynamic psychotherapy (Trowell *et al.*, 2007). There is also evidence that improvements in family functioning mediate changes in mood (Garoff *et al.*, 2012).

Moreover, there have been several studies of multifamily interventions for both depression and bipolar disorder (Miklowitz *et al.*, 2008; Fristad *et al.*, 2009), which show considerable promise. There are a growing number of treatment programs that include a multifamily component in the therapy for a range of problems and there is evidence that bringing groups of families together may improve outcomes (McKay *et al.*, 2011; MacPherson *et al.*, 2013) and is also a powerful way of addressing feelings of isolation, stigmatization, and helplessness that families often experience (Asen & Scholz, 2010); in these contexts, the family work is usually added to disorder-specific treatment.

Implications for clinical practice

As many have pointed out (e.g., Sackett *et al.*, 1996; Kazdin, 2008), evidence-based practice should not be understood simply as the adoption of treatments supported by results from randomized trials. For instance, the treatment research studies in anxiety and mood disorders indicate that a largely individual CBT and family-based CBT lead to similar outcomes at least in terms of symptom improvement. Nevertheless, it would be a mistake to conclude that the family, therefore, need not be involved in treatment. The potential positive effects go beyond improvements for the referred child and hopefully strengthen the network around the child and may provide protection for other vulnerable family members. Even putting aside the potential of the broader benefits and possibly better longer-term outcomes, family-based interventions have a clearly important contribution. At the very least individual and family-oriented treatments provide alternatives, the choice of which can be guided by factors other than efficacy. Many parents feel that they are to blame for their child's problem and a supportive nonblaming role in treatment can help to make them feel that they are a solution rather than the cause of the problem.

Even where there is clear evidence that family therapy is efficacious, implementing the research findings in clinical practice is by no means straightforward (see Chapter 36). The first limitation is our lack of understanding of the mechanisms of treatments and the difficulty therefore of defining what constitutes a distinct treatment. For example, the best researched areas of family therapy (behavior problems and substance misuse) have been dominated by the evaluation of several brand named therapies developed in the US (Multi-Systemic Therapy, Multi-Dimensional Family Therapy, Functional Family Therapy, and Brief Strategic Family Therapy). Notwithstanding the claims by the developers of these treatments as to the uniqueness of each approach and the need to implement the treatments strictly adhering to the treatment manuals, the evidence for this is weak. As the clinical commentary in a study by Baldwin *et al.* (2012) points out, the vast majority of the research has been undertaken by the developers and there is a lack of any significant comparison between the treatments. Many of the treatments are disseminated under license, making comparisons more difficult to undertake. The argument in favor of this is that this ensures that the treatments are evaluated and disseminated in an adherent way making them more robust. This, however, comes up against the second dissemination problem, namely the extent to which, and under what conditions, adherence improves outcomes. There are a number of studies undertaken by the developers of these treatments suggesting that improved adherence improves outcomes (e.g., Hogue & Liddle, 2009; Sexton & Turner, 2010). However, the broader literature on adherence shows a much more complicated picture indicating that adherence does not have a strong linear relationship with outcome (Barber *et al.*, 2006; Webb *et al.*, 2010) and may be moderated by factors such as therapeutic alliance, competence, and therapist experience (Castonguay *et al.*, 2010). The third

dissemination complexity concerns the role of service context in which treatments are delivered. This has been shown in a recent naturalistic study (House *et al.*, 2012) comparing specialist and nonspecialist outpatient services providing treatment for adolescent anorexia nervosa in different parts of London. Three fundamental difference characterized areas with access to specialist services: first, identification of those requiring treatment was 2–3 times higher than in areas with no specialist provisions, second, hospital admissions were 2–3 times lower in specialist areas and third, 80% of those referred to generic CAMHS (child and adolescent mental health services) were at some stage referred on to other services which was true of less than 20% of those referred straight to a specialist service. The impact of these differences far outweigh the differences between treatment outcomes found in randomized control trials (RCTs) and suggests that specialist expertise (which includes but is not limited to knowledge of evidence-based treatments), referrer and family expectation may play a greater role than the treatments themselves.

Conclusions

Family interventions have been established as an essential treatment within a multidisciplinary team when working with children and adolescents with increasingly strong evidence for its efficacy. We have emphasized that the role of the family in treatment needs to be considered broadly and not just as part of an evidence-based equation of treatment efficacy related to a specific problem although clearly with behavior problems, youth offending, substance misuse and also eating disorders family therapy should be considered a key intervention. A great deal more research is needed to gain a better understanding of how family interventions work to bring about change and the similarities and differences between the mechanisms of change of different treatments. Much of the current discussion about evidence-based practice is concerned with the relative contribution of model specific and common factors in psychotherapy (Sprenkle *et al.*, 2009; Duncan *et al.*, 2010) and the extent to which careful adherence to very precisely defined treatment models need to be balanced by flexibility and clinical judgment in tailoring treatments to the specific needs of individual families (Sexton *et al.*, 2008). Thus while our knowledge of what works is clearly increasing, our understanding of how treatments work and the way in which research evidence is best disseminated has still a long way to go.

CHAPTER 40

Relationship-based treatments

Jonathan Green

Child and Adolescent Psychiatry, Institute of Brain, Behaviour and Mental Health, University of Manchester and the Royal Manchester Children's Hospital, Manchester, UK

Introduction

“Relationship-based treatments” are defined in this chapter as those that have, as their prime aim, either the improvement of a child or adolescent's key relationships or else use relationships as a core mechanism through which they are delivered and generate psychological and behavioral change. The quality of early relationships with caregivers and others has a recognized impact on later social development, social competency, mental health and well-being and a central role in developmental science and developmental psychopathology. Additionally, much learning and development takes place within the context of social relating and is in that sense truly “social” learning. Theories of how maturational and extrinsic influences interact together at behavioral, cognitive, emotional and neural system levels within developmental psychopathology are increasingly important to the design of interventions.

The chapter covers three main areas: (i) interventions that aim to improve the relatedness between children and significant caregivers in early childhood, both in the context of parental risk such as trauma or mood disorder and child risk such as individual difference or atypical development; (ii) the nature and impact of the relationship between therapist and patient in the process of treatment, referring to non-specific factors such as the therapeutic alliance that operate across different forms of therapy; (iii) interventions in later childhood and adolescence that either have a particular focus on improving social relationships or are defined by the use of the therapist–patient relationship as a major mechanism for effecting change. Treatments are included for discussion if they are informed by modern developmental science and/or have an evidence base for the treatment itself or its key components. General approaches considered include Secure Base Therapy, Motivational Interviewing (MI) and Mentalization-Based Therapy (MBT); along with a number of specific forms of psychotherapy such as Short Term Psychodynamic Psychotherapy (STPP), Interpersonal Therapy

(IPT) and Cognitive Analytic Therapy (CAT). Not covered here are treatments marked by a more cognitive or social learning focus that are specifically addressed in other chapters, such as cognitive behavior therapy (CBT) (see Chapter 38), parent training (see Chapter 37) and multimodal approaches such as multisystemic therapy (see Chapter 50).

Taking a crosscutting approach, material in the chapter will overlap with a number of other chapters in this book, to which reference will be made.

Treatments targeted at early relationships

A number of interventions aim to improve early dyadic caregiver–infant and caregiver–child relationships, particular early infant attachment. These have been implemented and studied in the context both of known *parental risks* for relationship difficulties, such as unresolved trauma or mental illness; and *child risks* such as early maltreatment, temperamental vulnerability or other biological risk exposure.

Context of parental risk

Parent-mediated video-aided interventions

For interventions in infancy focused on attachment, a meta-analysis of 51 randomized trials (Bakermans-Kranenburg *et al.*, 2003) has suggested that developmentally based, carefully tailored, brief (<16 sessions) and individualized interventions often using video-aided techniques are most effective in optimizing attachment-related parental behaviors such as sensitive responding (overall $d = 0.45$); whereas general parental support or longer term therapy aimed at altering maternal mental state showed less effectiveness ($d = 0.27$). The subsequent impact of the treatment on infant development, however, is consistently less, with modest improvement found in infant insecure attachments ($d = 0.22$) and none on disorganized attachment ($d = 0.05$). In these interventions, caregivers typically review with the therapist videotapes of their naturalistic interactions

with their infant. The therapist uses the video material to help sensitize the caregiver to the signals of and meaning behind infant social communication. The focus on real time learning through videotape is a powerful way of increasing parental awareness, sensitivity, and enjoyment with their infant. An example of such intervention is the Video Intervention for Positive Parenting (VIPP; Juffer *et al.*, 2008), which has shown effectiveness in early parental risk and for children with vulnerable temperaments (Velderman *et al.*, 2006). Adaptation of the model shows positive impact on interaction and patterns of early feeding in mothers with eating disorder (Stein *et al.*, 2006) and an extension for preschool children with early externalizing behaviors incorporates positive disciplining practices (VIPP-Sensitive Discipline). This latter has been tested in a relatively large efficacy randomized control trial (RCT) ($N=237$, Van Zeijl *et al.*, 2006), showing positive effect on parental disciplining behaviors although not parental sensitivity; there was no overall effect on child externalizing behavior, but an improvement in child overactivity symptoms in a subset of families with high marital and daily hassle stress. In parents at significant risk, or showing early signs of, maltreatment of their children, an 8 week parent-mediated video-aided attachment-focused intervention in the early years (Moss *et al.*, 2011) showed success in improving observed parental sensitivity in the home, and this was associated with a shift in the child from insecure and disorganized child attachment behaviors toward more organized and secure attachments. There was, however, no robust change here in parent-rated child internalizing or externalizing behaviors. The “attachment and bio-behavioral catch up” (ABC) program developed by Dozier and colleagues has a similar focus on parental support, nurturing and video-aided intervention to improve responsiveness and sensitive responding to children in contexts of parents at risk of maltreating their child or whose child is in foster care (Dozier *et al.*, 2008; see Chapter 6).

Psychotherapeutic interventions

In contrast to the focus on detailed parent–infant interaction, psychotherapeutic approaches address the emotional and mental state of caregivers, who often have complex personal histories impacting on their parenting ability and relationships. A psychotherapy approach with depressed mothers and their toddlers at mean age 20 months showed a positive effect on infant attachment security at 36 months (Cicchetti *et al.*, 1999), but psychotherapy intervention (21 sessions over 1 year) in maltreating parents of children aged about 12 months showed no additional benefit over a psychoeducational intervention (25 sessions over 1 year), although both showed benefit compared with standard community services (Cicchetti *et al.*, 2006). Similar interventions focused on changing parents’ own underlying cognitions (“representations”) in relation to attachment relationships have found positive effects on maternal mood (Cooper *et al.*, 2003) and sensitivity (Murray *et al.*, 2003) but not on child attachment status (see Chapter 26).

Group support and counselling

Psychosocial support and counseling for caregivers is probably the most widely used intervention over the prenatal period or first 2 years. Three RCTs have shown benefits of such programmes on general maternal functioning and sensitivity in high social adversity situations but no associated effect on infant attachment (Barnard *et al.*, 1988; Beckwith, 1988; Murray *et al.*, 2003). By contrast, two studies showed no effect on maternal sensitivity but some increase in infant security over controls (Jacobson & Frye, 1991). Attachment-focused group interventions for parents have not been tested in randomized trials; observational studies indicate an increase in secure child attachment (Cassidy *et al.*, 2007) and reduction in attachment disorganization (Hoffman *et al.*, 2006); but this evidence is preliminary.

Context of child developmental risk or disability

There is a recent shift away from an exclusive focus on parenting sensitivity irrespective of child characteristics toward more consideration of individual differences in children. Video-aided parenting approaches have been used successfully to improve attachment and relatedness in infants at risk due to extreme or difficult temperaments (Van den Boom, 1994; Cassidy *et al.*, 2011); they have also been targeted at improving relationships between parents and children with developmental disability. Here, it is the child’s atypical development that is the main influence on impaired interaction and interaction-dependent development and outcomes. In autism for instance, developmental evidence (Wan *et al.*, 2013) suggests that infant atypicality is associated with disrupted parent–infant interaction. This disruption itself could then amplify the atypical trajectory and create poorer developmental outcomes through direct effect on the evolving social brain within environmentally expectant neural systems (Johnson, 2011), or at the level of relationship development, language, or general psychological development. Social communication interventions here work with parents (or for older children, teaching assistants, or peers), often using video-aided methods, to enhance awareness of the child’s communication and to enhance dyadic communication designed to promote child social communication, attention, shared enjoyment, and language. Such interventions have been recommended for consideration by UK National Institute for Health and Care Excellence in treatment of core features of autism (Kendall *et al.*, 2013). An RCT ($n=152$) of a 12 month parent-mediated intervention of this kind for preschool children with autism (Green *et al.*, 2010) showed strong effects on parental synchronous communication responses to the child (effect size 1.22) and child dyadic communication to parent (effect size 0.41), but an attenuation in relation to generalized autism symptoms (effect size 0.24, non significant on ADOS-G), despite parental reports of language, social communication, and family well-being being positive. An RCT of another parent-mediated social communication intervention

programme that focused on joint engagement ($n = 38$) showed a similar pattern of positive short-range effects on the targeted interaction variables (Kasari *et al.*, 2010), while a related intervention with separate procedures to enhance joint attention and symbolic play in relation to language outcomes ($n = 58$) that worked more directly with the child reported additional downstream improvement on assessed language (Kasari *et al.*, 2008), although this has not been replicated (Kaale *et al.*, 2014). These kinds of intervention studies presuppose that children with atypical neurodevelopment have the same relational needs as children with neuro-typical development and that the difficulties in interaction and relational development consequent on their disability may act in turn to amplify adverse mental health and social outcomes. The evidence suggests that such interventions can positively shift atypical transactional developmental patterns in the short term; the challenge is how to generalize and sustain these child changes through time.

Differential susceptibility theory (Belsky *et al.*, 2007) suggests that children may differ in their sensitivity to both positive and negative aspects of the environment and predicts that some children with atypical development may respond particularly positively to the improved environment through social interventions of this kind. Partial support of this comes from the treatment arms of infancy RCTs (Velderman *et al.*, 2006; Cassidy *et al.*, 2011) showing that brief parent-mediated interventions improving sensitivity are differentially efficacious in infants with high temperamental reactivity.

Summary

Across a variety of risk contexts, including parental psychosocial adversity, maltreatment history, or mood disorder and childhood developmental disability or temperamental vulnerability, interventions can improve parental behaviors understood to promote positive developmental relationships. Associated gains in infant or child dyadic behaviors such as communication initiations or attachment behaviors toward the parent are found, but attenuated compared to the effect on parental behaviors. Aspects of childhood vulnerability may be associated with increased response to such interventions. The interventions themselves are flexibly adapted to specific child needs, and in this the intervention design mirrors the kind of adaptive responding in parents that leads to increased sensitivity. There is well-established short-term effectiveness and it is theoretically reasonable to hope that altering relationship dynamics in this way will have longer-term benefits on child development; however, evidence for this downstream impact is currently much weaker, and this is even true of the non blinded parent-rated outcomes which would be expected to be most sensitive to treatment effect. Most of these interventions take an individual approach within which specific attention can be given to the needs of the dyad and there has been little testing of group approaches. For the future, there are two challenges: firstly to show generalization of treatment effect beyond the context of

the specific dyadic relationship, including adding additional intervention elements to promote such generalization; secondly, to demonstrate sustained impact through time, again including additional elements such as repeated intervention or booster sessions to maximize developmental gains.

Therapist–patient relationship as a mode of treatment

Focus on the therapist–patient relationship as a mechanism of therapeutic change is a central theoretical feature of various traditions in psychotherapy, including transference theory in psychoanalysis and notions of ‘unconditional positive regard’ in humanistic traditions. Construed as the ‘therapeutic alliance’, it has been increasingly understood and studied as a non-specific therapeutic factor operating across different kinds of psychotherapy and broader treatments.

Therapeutic alliance

The therapeutic alliance is a term encompassing a variety of relational variables between patient and therapist (Green, 2006; see Chapter 36). Its description and measurement has evolved in parallel with changing theory (Elvins *et al.*, 2008); an empirically based review (Hougaard, 1994) identified key dimensions of “Personal Alliance,” the relationship of engagement and personal trust between therapist and client, and “Task Alliance,” a more contractual relationship around agreement on the focus, goals, method and depth of the intervention. These two dimensions were generally inter-correlated. The impact of therapeutic alliance is observed across many different types of intervention, extending well beyond psychotherapy. In adult mental health, for instance, an important study (Krupnick *et al.*, 1996) independently measured alliance from sessional transcripts in a large RCT for depression, with intervention arms ranging from medication management to cognitive therapy. The quality of the measured alliance was independent of the type of treatment, identity of therapist, or baseline symptom severity. It was, however, highly correlated with treatment outcome across *all arms* of the trial (overall $r = 0.46$) and predicted remission of depression caseness (OR 17.2) more strongly than the individual treatments themselves. Subsequent broader meta-analysis across both adult (Martin *et al.*, 2000) and child and adolescent (Shirk & Karver, 2003) mental health studies found an overall robust albeit modest association between alliance quality and outcome; in the child studies, this was $r = 0.24$ across 23 studies of differing methodology, independent of child age and type of treatment. Alliance is, however, a complex phenomenon and there are methodological limitations on some of these reports (Kazdin & Nock, 2003; Green, 2006; Dunn & Bentall, 2007); for instance, 57% of 49 studies in a recent meta-analysis (Karver *et al.*, 2006) showed significant problems with common method and rater biases (for instance, the same person rating both alliance and outcome) that may inflate apparent alliance effects. Moreover, because alliance emerges *during treatment*

it is by definition a post-baseline variable that is subject to confounds that cannot be controlled by initial randomization in trials. Newer analytic methods addressing these problems still confirm a modest but significant impact of alliance on treatment outcomes in adult schizophrenia (Dunn & Bentall, 2007) and evidence of similar effect in adolescent depression (Elvins, 2012).

Therapist qualities such as active listening, accurate empathy, and commitment, as well as “direct influence” from good communication, clear treatment rationale, and collaborative planning all showed a moderate to strong association with alliance quality in a meta-analysis of 49 studies (Karver *et al.*, 2006), but therapist self-disclosure showed no relationship. Patient characteristics are also important. The alliance is usually found to be independent of severity of baseline symptomatology, but it is theoretically likely that the patient’s prior capacity to form general social relationships of collaboration and trust will influence their capacity to form a productive therapeutic alliance in the therapy setting. An effect of child pretreatment social competence and intellectual functioning on early alliance was found in an RCT for child behavior problems ($n = 97$; Kazdin & Durbin, 2012), and pretreatment personality disorder independently predicted alliance and outcome in an RCT of adolescents with repeated self-harm (Ayodeji *et al.*, 2015).

The evidence thus supports the modest but important impact of quality of therapist–patient alliance relationship on outcomes across many intervention types, but we still do not know exactly how the alliance impacts on outcome. Does it just work by promoting good engagement with an efficacious treatment or does it have its own independent therapeutic effect in parallel to the specific treatment technique? Do prior patient qualities associated with good alliance formation themselves predict a good outcome? These questions have important implications for clinical practice and training in relation to what actually are the important components of successful treatment; and in research design, where careful methodological thinking is necessary to test the complexities of alliance phenomena (Kraemer *et al.*, 2002). We await experimental trials of whether specific methods to enhance alliance *alone* would be as effective as specific intervention protocols (a key question). Notwithstanding this, there is enough evidence to suggest that promotion of the alliance should be a core feature of professional training and intervention development; understanding family and child variables predicting alliance will also help us better individualize treatment approaches.

Alliance, treatment fidelity, and adherence

The effect of non specific factors such as alliance suggests that fidelity to a specific model may not always be the most important influence on treatment outcome. However, some studies do suggest an association between better model fidelity and outcome (for instance in Multisystemic Therapy; Schoenwald *et al.*, 2000). Maximizing *both* the quality of alliance and model fidelity may naturally have additive value; however, their relative

effect is an important empirical question for training and service planning and has been under-studied. Castonguay *et al.* (1996) for instance directly compared quality of therapeutic alliance, the relational focus of sessions and therapist fidelity to a cognitively-focused CBT protocol, as predictors of outcome in adult depression. Alliance and relationship focus were found to carry the bulk of the treatment effect, and a rigid adherence to the cognitive model in the face of patient resistance tended to produce a poor outcome. This study emphasizes the dangers of “cook book” therapy routines and the need for manualized models of any kind to be applied with flexibility and sensitivity to patient need; but the broader question of the relative value of different treatment types as against non specific factors remains understudied. This will be considered further below in relation to individual psychotherapies.

Relational aspects are also implicated in the important area of treatment adherence. A study of 344 children (7–18 years) attending community mental health clinics in the US (Garcia & Weisz, 2002) found that premature termination of treatment was more associated with problems in the “therapeutic relationship” than lack of family motivation, practical difficulties, time concerns, or perceived lack of symptom improvement. Breaking off treatment in this way might arguably be protective; in a study of adult schizophrenia, continuing with session attendance in the face of a poor alliance actually produced adverse outcomes compared to no treatment (Dunn *et al.*, 2007); a similar finding is suggested in adolescent depression (Elvins, 2012). More specialist techniques of engagement in “hard-to-reach” groups has had some success; discussed in the following sections on MI and Mentalization Based Therapy.

Attachment-based therapy

Shirk and Russell (1996) argued that the large literature on interpersonal processes in developmental psychology should be applied to the study of the therapeutic relationship. Therapist qualities promoting a positive personal alliance are similar to those described in the developmental attachment literature as promoting secure-base attachment. In John Bowlby’s concept of “secure base” therapy (Bowlby, 1988), this idea is extended to form the core of the therapy process. Bowlby used a juxtaposition central to attachment theory; that proximity to a secure attachment figure assuages anxiety which then acts to facilitate an exploratory movement away from the attachment figure toward exploration, development, other-directedness, and new learning. In Bowlby’s formulation, the initial therapy task is to provide an interpersonal context within which the patient can work through attachment difficulties to experience the equivalent of such a “secure base” with the therapist; once achieved the patient may then naturally enter an “exploratory” mode in which problem solving and new learning in relation to the realities of the patient’s life would emerge. In this solution-focused phase of therapy, the therapist might well act to guide or facilitate but because the ideas came largely from the patient they would be most likely appropriate to circumstance

and experienced as self-generated and empowering. Bowlby also maintained that this solution-focused phase of therapy should not be directed by prior theory, but left open to be influenced by knowledge from developmental science. He thus crafted a therapist stance that was responsive, in that the patient would provide themselves many of the ideas for change, and also in the therapist's openness to emerging scientific understanding. This stance marked a break from the theory-driven models underlying psychoanalytic transference and has had a formative legacy for subsequent developments. Bowlby's articulation of a more collaborative therapeutic stance with the patient has become the norm across most varieties of psychotherapeutic work. His opening up of the content of therapeutic discussion to the findings of developmental science allows the possibility of flexible therapeutic strategies in dialogue with research. The result can be seen in contemporary developments such as MBT (see below) and in the adaptations of therapeutic approaches to emerging understanding of developmental disorders considered earlier.

Bowlby's formulation, however, begs a number of questions of detail, which have been insufficiently explored (Eagle, 2006). For instance, what is the process of therapeutic change here? Is a "corrective emotional experience" with the therapist enough to alter the internal assumptions and working models of attachment within the therapeutic relationship, or is some further procedure necessary? Detailed technical and procedural aspects of helping change in this model are beyond the scope of this chapter; but will involve inevitably a range of elements at the therapist's disposal, including cognitive restructuring, emotional rehearsal, desensitization, management of anxiety, modeling and others. In contemporary practice, therapeutic procedures can be informed by developmental research as to moderators of change from longitudinal or epidemiological studies; for instance, when working with vulnerable female adolescents, planning or the choice of a partner might be critical elements to consider and in working with children with externalizing behaviors, aspects of attention deficit hyperactivity disorder (ADHD) or Callous and Unemotional Traits might be important. The point is the integration of psychological therapy practice with empirical information from emerging developmental studies. In Bowlby's formulation a common feature is the initial need to engage the patient into a secure alliance. This will be easier in some patients than others, depending on their prior attachment and interpersonal experience. Bowlby's procedures were predicated on his clients having underlying difficulties with insecure relationships; next we consider adaptations to more complex ambivalence and disorganized mental states.

Motivational interviewing

It is a subtle paradox—observed also in other kinds of reciprocal relationship such as childhood attachment or joint attention in infancy—that while clinicians will wish to enhance patient alliance and relatedness in treatment, they cannot impose or control this—indeed trying to do so is likely to be particularly counterproductive. Motivational Interviewing (MI) is

an approach to this paradox that was first developed in the context of substance misuse in adults but whose principles have been generalized to child and adolescent work (Baer & Peterson, 2002; Naar-King & Suarez, 2011). The interpersonal therapeutic stance in MI pays great attention to the details of the therapists' communication, working to enhance alliance and to identify discrepancies between the client's current situation or behavior and their own values or wishes, thus eliciting and reinforcing the seeds of a motivation towards change. In keeping with a respect for patient autonomy, "resistance to change" is considered in interpersonal terms as a meaningful reaction to external pressure or demand; the therapist sidesteps this by not suggesting or imposing change themselves but rather with a pattern of reflective questioning to identify and reinforce "change talk" or elements of change behaviors emerging in the client (reminiscent of the emerging solution-focused talk identified by Bowlby). Similarly there are techniques to reduce "sustain" ideas, which serve to maintain the status quo. MI theorists stress that this is not just a set of "techniques"; rather a sustained interpersonal stance with the patient, which reflects, questions and affirms their control of the path toward change. MI thus builds on alliance theory through articulating a set of therapeutic skills particularly well adapted for situations where patients are ambivalent or resistant to change: maintaining collaboration while also undertaking structured assessment or other questioning. MI can be applied to conditions such as substance misuse or eating disorder but also to therapeutic regimes such as medication adherence or behavioral programs. The stance is well adapted to the sensitivities of childhood and adolescence in which young people have often not actively chosen to seek treatment and experience external family or social pressure.

There is limited empirical evidence on the effectiveness of MI in childhood and adolescence. A preliminary study has shown that the addition of MI as a precursor to CBT in adolescent OCD demonstrated faster treatment gains compared to psychoeducation plus CBT (Merlo *et al.*, 2010). In anorexia nervosa, a large RCT comparing outpatient CBT plus MI with standard outpatient and inpatient care (Gowers *et al.*, 2007), found motivation for the therapy improved after the initial MI session and the MI + CBT arm as more cost-effective than the comparators. A variation on MI, Motivational Enhancement Training (MET), improved the speed and cost effectiveness of family therapy in reducing bulimic symptoms (Schmidt *et al.*, 2007).

Psychotherapeutic treatments for children and adolescents

Mentalization based treatment

A further elaboration of the therapeutic relationship in treatment, particularly in the context of more complex psychopathology such as borderline states, is found in MBT.

This is possibly the most important therapeutic extension to attachment-related therapy since Bowlby's secure-base treatment, adding to it a more developed theory of mentalization. It is particularly applicable in the context of patients whose mental state is highly unstable or showing borderline personality traits, where MBT takes evidence-based theory to illuminate the therapeutic relationship. The empirical basis of MBT arises from work following Bowlby on states of disorganized attachment, commonly related to intergenerational trauma. Disorganized attachment is associated with significant child psychopathology and in adults particularly with borderline mental states. One of the development consequences of disorganized attachment is a relative failure of reflective function or "mentalization"; and it is the particular focus of MBT to recover such reflective function in patients' lives as a condition for developing mental health (Fonagy *et al.*, 2002). Like CBT, therapist and patient in MBT occupy a shared empirical stance—but whereas in CBT the object of common regard is the pattern of client cognition in relation to affect and behavior, in MBT an important focus is the therapeutic relationship itself and a capacity to reflect on the mental states (thoughts, feelings and beliefs) arising within it. The mechanism of treatment is also different. In CBT, techniques of probabilistic reasoning are used, whereas in MBT, the therapist models for the patient in real time within the therapy how action, reflection, and insight have to be worked for authentically. The patient experiences the therapist monitoring and correcting their own mentalizing failures, "not knowing" prior answers, accepting differences in therapist and patient perspectives, actively questioning ("what questions") rather than explaining ("why questions"), and clarifying unclear communication (Bateman & Fonagy, 2008).

MBT is not presented as a "new form" of psychotherapy—rather it offers series of technical approaches to promote reflective function, which can be applied in the context of diverse forms of therapy. In that sense (although the details of approach are different), it bears some comparison with MI and alliance theory, as well as having origins in Bowlby's therapeutic orientation. Each of these approaches is grounded in empirical research and takes a more "modular" approach to elements of therapeutic strategy in contrast to self-contained "named" or "labeled" therapies. The logical extension of this approach is an empirically based psychotherapy combining evidenced effective elements utilized according to individual patient need. This is not to advocate an arbitrary "pick-and-mix," because coherence is important; but instead for a reconceptualization of what promotes therapeutic change in specific conditions. Bateman has elaborated this idea in the context of Borderline Personality Disorder (Bateman, 2012).

MBT has been adapted in a number of different settings for work with children and families (Midgley & Vrouva, 2012). In an RCT with adolescents who self-harmed and had depression, MBT-A was compared with treatment as usual, which was predominantly CBT and counseling intervention

($n = 80$; Rossouw & Fonagy, 2012), MBT-A was delivered in weekly individual sessions with monthly family-based sessions focused on affect regulation and mentalization. A moderate effect size in favor of MBT-A was found in both self-reported and interview-based self-harm estimates after 1 year of treatment, most strikingly in numbers reporting no self harm over 3 months ($\chi^2_5, p = 0.01$; NNT (number needed to treat) 3.66). Treatment effect was associated with relative reduction in self-reported attachment avoidance and borderline features, with evidence of mediation from both on the reduction in self harm. This study needs replication on larger samples (there was considerable treatment dropout in both arms) but is an important preliminary result given the lack of treatment effect found over many years in other interventions for the important problem of adolescent self harm (Ougrin *et al.*, 2012). Related developments are an adaptation of MBT for mood disorders called Dynamic Interpersonal Therapy (DIT, Lemma *et al.*, 2011), a version for working with families (MBT-F; Keaveny *et al.*, 2012) and an adaptation of a mentalizing focus within systemic multidisciplinary work for "hard to reach" young people, called AMBIT (Bevington *et al.*, 2013). Each of these approaches is in development and has yet to be evaluated using randomized clinical trials.

Short term psychodynamic psychotherapy (STPP)

Any evaluation of current psychodynamic psychotherapy depends on its definition. One influential account (Shedler, 2010) takes a process orientated generic approach, defining psychodynamic psychotherapy in terms of its focus on a client's emotions and attempts to avoid distressing thoughts and feelings, discussion of past experiences and interpersonal relationships, exploration of wishes and fantasies, and relevance of the current therapy relationship. Other contemporary practitioners (e.g., Delgado, 2008) emphasize a more traditional psychoanalytic theory-driven account, giving central importance to the unconscious in mental functioning, the existence of internalised unconscious conflicts, the symbolic meaning of behaviors and the analysis in therapy of transference-based thoughts and behaviors. The more generic process-orientated account underlies recent reviews of the adult literature (Shedler, 2010), arguing for the increasing evidence of effectiveness of psychotherapy intervention and asserting that psychodynamic principles are common relational factors, which carry the treatment effect in a number of other treatment methods (for instance CBT). This makes psychodynamic therapy theory convergent with common-factors theory and therapeutic alliance. A narrative review of child and adolescent STPP (Midgley & Kennedy, 2011) included any trial described by its authors as involving STPP, but because such studies rarely used manuals (a situation that is improving), it is difficult to know what really is being studied. The review identified eight randomized trials but most had significant methodological difficulties mainly related to small sample size. In a randomized equivalence trial

of a manualized STPP versus family therapy for child depression, Trowell *et al.* (2007) found that both groups improved, with no between-group effects. A quasi-experimental non randomized trial of an 11 week manualized form of STPP for anxiety and depression in middle childhood was studied against usual care in Italy (Muratori *et al.*, 2003). The focus was on parent-mediated treatment but with the addition of child sessions. No treatment effect was observed at 6 months but at 2 year follow-up an effect in favor of experimental treatment was observed on parent-CBCL, particularly on anxiety-related symptoms and in clinician Childhood Global Assessment Scale (both outcomes were non-blinded assessments). A recent meta-analysis of short-term (under 40 sessions) STPP for children and adolescents (Abbass *et al.*, 2013) found 11 RCT or quasi-experimental studies (total $n=655$) with mean child age of 11.3 years (SD 2.7). Studies varied greatly in size and quality, overall classed as moderate. The majority represented equivalence trials against a total of 13 comparator treatments such as CBT, long-term psychotherapy, IPT, FT; only three studies had an attention control or non treatment control group. Patient groups included emotional disorder, mixed disorders, anxiety disorders and personality problems. Overall, there were generally high within-group effects in both arms of studies but very few between-group differences separating STPP from comparators. Sensitivity analysis suggested that there might be the possibility of some sleeper effects with increasing gains at follow-up (echoing findings also in adulthood; Shedler, 2010) and a positive effect of therapist adherence to the model. The greatest between-group effect in favor of STPP was found in mixed disorders and emotional/behavioral disorders; CBT comparators were more effective than STPP in mood disorder. The findings from this meta-analysis suggest that short-term psychoanalytic psychotherapy may fare no worse than comparators or treatment as usual in some contexts. However, it is difficult to make robust inference on efficacy given the lack of between group differences and non equivalence controls. The body of trial evidence for psychotherapy is considerably smaller than that for CBT or even family therapy, with the best evidence in relation to mood disorder. The quality of intervention studies is showing some signs of improvement, for instance, the large IMPACT trial underway of STPP, CBT, and specialist clinical care for adolescent depression shows considerable increase in sophistication over previous psychotherapy studies, (Goodyer *et al.*, 2011).

Interpersonal psychotherapy

IPT is a manualized psychotherapy that focuses on the reciprocal relationship between mood-state and the client's current real-world social relationships; it is pragmatic rather than theory driven in its focus on disruption in interpersonal relationships as an antecedent for mood change and improvement of relationships as a route into improving mood (Weissman *et al.*, 2000). IPT is time-limited (12–16 weekly sessions) and particularly focused on and evidenced in adults for depressive

illness, although adaptations for other mood and eating disorders have been made. Developed from a root in counseling rather than dynamic psychotherapy, there is less emphasis than STPP or MBT on the interpersonal relationship between therapist and patient during treatment, although the establishment of therapeutic alliance is incorporated into the therapy process. In the assessment phase of IPT, the client undertakes a review of current relationships, identifies how their mood problems interact with these and the relationship features associated with the onset of mood disorder. This allows the selection of a focus for therapeutic work from a number of typical areas of difficulty in depression, such as grief after the loss of a loved one, conflict in significant relationships, difficulties adapting to changes in relationships or life circumstances; or difficulties stemming from social isolation. In the adaptation of IPT for adolescence (IPT-A) additional areas are included such as separation from parents, single parent families, development of romantic relationships and initial experience with death of a relative or friend. In the treatment phase, the client learns to link changes in mood to events occurring in his/her relationships within the problem areas, identifies communication and problem-solving techniques for that problem area and practises these in the therapy sessions prior to using them outside of the session in the context of significant relationships (Mufson, 2010). IPT-A thus aims to help the adolescent identify and develop more adaptive methods for dealing with the interpersonal issues associated with the onset or maintenance of their depression. Although the treatment involves primarily individual sessions with the teenager, parents are asked to participate in a few sessions to receive education about depression, to address any relationship difficulties that may be occurring between the adolescent and his/her parents and to help support the adolescent's treatment. The final sessions work with issues of termination of treatment and maintenance of change.

In adolescents, an initial RCT ($n=48$; Mufson *et al.*, 1999) found that 18 (75%) of 24 patients who completed IPT-A met recovery criterion on the Hamilton Rating Scale for Depression at 12 week endpoint compared to 11 (46%) in the control condition ($p=0.04$, no effect size (ES) quoted), but there was no group effect in suicidality or global functioning or self-rated Beck depression inventory. A different parallel adaptation of the adult IPT model was tested in Puerto Rico in an equivalence trial against CBT and wait-list (Rossello & Bernal, 1999). Both IPT ($n=23$; ES 0.72) and CBT ($n=25$; ES 0.43) showed improvement over wait-list ($n=23$) but endpoint was self-report and baseline inclusion was not standardized. A slightly larger community-based effectiveness study (Mufson *et al.*, 2004) implemented IPT-A with community-based physicians in frontline school health clinics for 63 low-income depressed adolescents. IPT-A showed benefits over treatment as usual on clinician-rated depression scores (Hamilton Depression Inventory; ES 0.5, $p=0.04$) and global functioning (Child Global Assessment Scale; ES 0.54, $p=0.04$) in ITT (intention to treat) analysis. Post hoc analysis suggested that high level of

conflict with mother and friends at baseline moderated greater treatment effect (Gunlicks-Stoessel *et al.*, 2010). There were limitations around internal validity and sample size indicating the need for further replication; a study in Taiwan (Tang *et al.*, 2009) has recruited adolescents screened in school and diagnosed with moderate to severe depression and suicidality, randomized to a modified shortened form of IPT-A ($n = 35$) against in-school counseling ($n = 38$). The IPT group showed significant improvement over TAU on self-rated Beck Depression, Anxiety and Hopelessness Inventories at the 6-week endpoint in this trial. IPT-A thus has a promising evidence base for adolescent depression and has been evaluated in community settings (see Chapter 63).

Cognitive analytic therapy

CAT is a structured short-term form of psychotherapy that integrates psychodynamic principles with a cognitive focus based on personal construct theory. It is probably the closest to CBT of the psychotherapies and takes a shared stance toward developing a formulation with the patient and tackling cognitive traps, dilemmas and snags in therapeutic progress. CAT differs from IPT in greater use of the therapist–patient relationship in the therapy process and a theoretical focus on the effects of early experience. In the early stages, there is development of a shared written formulation of the key problems for the patient, their origins in previous relationships and experiences and the priorities for therapeutic change. The treatment phase uses problem-orientated discussion and reflection on the therapeutic relationship to gain insight into the operation of learned patterns both in and out of the therapy room and how these relate to the problems in focus. There is relatively little systematic RCT study of CAT and little evidence in adolescence but one study on borderline personality disorder and self harm showed no group effect over general clinical care (Chanen *et al.*, 2008).

Summary

Relationship-based treatments range from a core of process research into common factors across different therapies; to incorporation within an attachment framework around secure base therapy; and then elaboration for difficult client groups, such as those with ambivalent or resistant motivation and complex borderline mental states. Quality of therapist–patient relationship within therapeutic alliance shows consistent modest effects on treatment outcome across a number of types of therapy, although methodology may have historically inflated some of these alliance–outcome correlations. Alliance is affected by prior patient social and psychological functioning as well as therapist behaviors. Bowlby’s secure base therapy develops the idea of attachment-relatedness between patient and therapist into a core component of treatment, underpinned by research into insecure attachment-related psychopathology. MBT extends this idea to address the more complex psychopathology associated with disorganized attachment and unstable mental states and MI takes technical development of therapeutic

communication in a different direction to address ambivalence and resistance to change. Each of these developments consist of theory-based generic techniques which are designed to be applied across the range of “named” treatment types—indeed there is evidence that it is these non-specific relational factors in therapy that often carry the positive effect of treatment. MBT and MI have particular added value for clients traditionally hard to reach by psychotherapy. Of specific “labeled” therapies: STPP shares some common therapeutic characteristics with the attachment-based therapies and a set of similar relationship-based therapeutic skills, but it is differentiated by therapy content and theory of change based on historical psychoanalytic theory, with little evidenced rationale and variably operationalized in different STPP models. Manualization and systematic testing of STPP approaches has only just begun and the evidence is preliminary. IPT in contrast has a simpler style originating more in humanistic counseling and is focused on approaches to optimize patient social functioning. It has a growing evidence base for depressive disorders in relatively uncomplicated client contexts. CAT is structured and cognitively based with influences from personal construct theory but its evidence base in adolescence is slim.

Implementation science

Each of these relationship-based techniques—building alliance, using secure base theory as a skill in generic therapy and the more complex differentiated skills in MBT and MI—are robust core skill sets with an evidence base that should be incorporated into systematic training of child mental health professionals. Implementation science (Eccles *et al.*, 2009; Green, 2012) looks to identify the process and barriers to implementation at a practitioner, system and organizational level. At a practitioner level, training is available for these approaches, but the success of cognitively oriented manualized treatments in recent years may have led to less awareness of these relational techniques. On the other hand, they are at the core of traditional client centred therapeutic practice and are intuitively appealing to many professionals, who often prefer a relational approach (Castonguay *et al.*, 1996; Shenley, 2012) and consider the therapeutic relationship is a key component of practice and outcome (Kazdin *et al.*, 1990; Siegel *et al.*, 1990). At a systems level the introduction in England of the “increasing access to psychological treatment” (IAPT) initiative provides an opportunity to standardize implementation and training in approaches that have empirical support and will increase practice quality. Traditionally psychotherapies have been considered as intensive and expensive; however, the difficulty of helping the increasingly complex cases that access child mental health services and the success of some of these complex theory-based approaches in tackling such difficulties provide a counterbalancing argument. The kind of process-orientated approach advocated by alliance theory, MI and MBT lends itself to flexible usage and empirical

testing, which needs to embrace process research and equivalence trials designed to establish the most appropriate treatment methods for different disorders.

Treatment selection

For relationship-based treatments taken as a whole, the theory and current evidence reviewed here suggests that treatment selection be informed by the quality of prior relationship experience and capacity for social functioning. This can be assessed from clinical and developmental history supplemented with measures such as Strengths and Difficulties Questionnaire (SDQ), and attachment-related questionnaires such as the relationships questionnaire (Bartholomew & Horowitz, 1991). A positive prior social functioning and relationship suggests that a positive therapeutic alliance is likely and then a variety of therapeutic modalities have a good chance of effectiveness, with little current evidence that one therapeutic modality has advantage over another except for patient or therapist preference. For cases with disrupted or vulnerable prior relationships or an insecure attachment organisation, therapeutic alliance will be harder and specific techniques of the kind outlined in Bowlby's secure base therapy are needed. Cases presenting with motivational conflict in relation to change will need more sophisticated techniques to establish a therapeutic alliance, such as MI. Finally, there are cases with evidence of a disorganized attachment history, inconsistent relationships, and unstable mental state, often with a history of unresolved trauma; such as young people with borderline personality development, severe relational disturbance, or self-harm. Here, much attention needs to be paid to the establishment of the therapeutic alliance and the best-evidenced approach currently is Mentalization-Based techniques, which can then be combined with an appropriate evidence-based modality of choice. Patients who have no progress in one modality should not be discharged without escalation to a higher risk pathway to attempt further engagement.

Global health

A disproportionate number of young people live in Low and Medium Income Countries (LMIC) and it is a priority for the global health agenda to address early developmental mental health in these countries (Collins *et al.*, 2011). Recent review (Kieling *et al.*, 2011; see Chapter 16) has identified some adaptation of early relationship-focused interventions to LMIC. These include early stimulation intervention for parents and children to improve parental responsiveness in Ethiopia (Klein & Rye, 2004), Russia (St Petersburg Orphanage Team, 2008) and Turkey (Kagitcibasi *et al.*, 2009) and in relation to child disability in Vietnam (Shin *et al.*, 2009). No studies into the implementation of specific psychotherapies with older children or adults are reported. There should be no reason why therapeutic alliance and relationship-based work should not form as central a

part of mental health provision in LMIC as in high-income countries and there is an urgent need to adapt, test, and deliver evidence-based interventions to LMIC. The core therapeutic modular skills described earlier are relatively accessible and intuitive, but would need systematizing and training for an adaptation to global health.

CHAPTER 41

Educational interventions for children's learning difficulties

Charles Hulme¹ and Monica Melby-Lervåg²

¹Division of Psychology and Language Sciences, University College London, UK

²Department of Special Needs Education, University of Oslo, Norway

Conceptual and methodological issues

Educational or psychological interventions, whatever they are for, should be based on sound principles. Preferably, interventions should be based on a theory of the nature and causes of a disorder that the intervention is designed to help. It is worth emphasizing that the fields of education and special education are plagued by interventions that lack a sound theoretical rationale. It is always possible that such interventions will have effects, but we should demand very high levels of evidence to convince us that interventions that are not based on a sound theoretical foundation really are effective.

We would emphasize that clinicians should evaluate claims for the effectiveness of new educational treatments with caution. For any proposed treatment, a clinician should ask two basic questions: (1) Is the proposed intervention theoretically plausible (i.e., does the intervention directly target a skill that is deficient in a given population, or target a process which has been identified as a likely cause of a disorder)? (2) If the answer to question (1) is positive, is there evidence from one or more randomized controlled trials (RCTs) to indicate that the intervention has beneficial effects (with reasonable effect sizes)?

In this chapter, we will concentrate on interventions for which there is good evidence for their effectiveness. We will not deal with interventions for which we believe evidence for their effectiveness is lacking or negative. Two examples of such interventions would be the Dore programme which focussed on training balance skills (Reynolds *et al.*, 2003) and the use of colored overlays or lenses, both of which appear to be ineffective as treatments for dyslexia (Snowling & Hulme, 2003; Henderson *et al.*, 2012). Our silence in this chapter on these interventions (and many others that lack a sound theoretical rationale) reflects our judgement that adequate evidence for their efficacy is simply lacking.

Although methodological issues have been dealt with elsewhere (see Chapter 14), we believe that it is important to emphasize the types of evidence that can establish that interventions “work.” In practice, this means the use of RCTs, quasi-experiments, or regression discontinuity designs. In the sections that follow, we will summarize a great deal of evidence (mostly from RCTs). The studies we review show that a range of educational interventions have been developed that are effective when delivered to children selected for having difficulties in developing key educational skills (problems of reading accuracy and fluency, problems of reading comprehension and problems with arithmetic skills). The studies usually involve specialist teaching delivered either to individual children or children in small groups.

Dyslexia and decoding impairments

Nature and causes of dyslexia and decoding impairments

Dyslexia, a severe difficulty in learning to read (in the sense of recognizing printed words accurately and fluently), is a relatively common disorder. Historically, dyslexia was typically defined using a discrepancy definition whereby a child's reading attainment needed to be out of line with their age and IQ (e.g., Rutter & Yule, 1975). Such a definition though still widely used has fallen from favor and DSM-5 makes no explicit reference to this (see Chapter 53). For children within the normal range of intellectual ability (IQs above 70), IQ appears only weakly correlated with reading accuracy and there is little evidence that IQ is predictive of variations in children's response to specialist reading instruction to improve decoding skills (e.g., Hatcher & Hulme, 1999).

Dyslexia is typically diagnosed when a person has severe difficulties with reading accuracy as assessed by a well standardized test. Given that reading skills have a continuous distribution in the population, the cut-off point for defining “dyslexia” is inherently arbitrary. Epidemiological studies suggest that, depending on where the diagnostic cut off is set, dyslexia affects approximately 3–8% of children (Peterson & Pennington, 2012). Decoding problems will not only affect the ability to read accurately at a word level, but also impair reading fluency and reading comprehension (Hulme & Snowling, 2009).

The currently accepted view is that the most powerful causal risk factor for dyslexia lies in the phonological system of language (i.e., the system responsible for representing sound structure of spoken words, see Chapter 53). Although the precise nature of this phonological deficit has been much debated, it appears that phonemic skills (being able to identify and manipulate the constituent sounds in spoken words) measured in children at the earliest stages of learning to read are closely related to the growth in children’s word reading skills (Melby-Lervåg, *et al.*, 2012). On this basis, it has been argued that the core problem in dyslexia is a difficulty in creating well-specified phonemic representations of speech (Hulme & Snowling, 2009). These findings have important applied implications because they suggest that the early teaching of reading, and the remedial teaching given to children with dyslexia, should emphasize the direct teaching of phonemic skills.

However, another key problem for children with dyslexia is learning letter-sound correspondences and poor letter-sound knowledge is another longitudinal predictor of learning to read (Lervåg *et al.*, 2009). Furthermore, analyses from an intervention designed to improve decoding skills in children at risk of reading difficulties showed that improvements in phoneme awareness (the ability to identify and manipulate the individual speech sounds in spoken words) and letter-sound knowledge at the end of the intervention were two key mediators of subsequent increases in word level reading skills (Hulme *et al.*, 2012). This suggests that children with weak word reading skills require help targeting phonemic awareness and letter-sound knowledge. However, it is important to emphasize that to be maximally effective, such interventions also need to be coupled with direct instruction in word recognition and book reading practice (Hatcher *et al.*, 1994).

Interventions targeting phonology

Meta-analyses of outcome studies

Several meta-analyses have been published summarizing the effectiveness of phonological interventions designed to improve reading skills in children with reading difficulties (Bus & van Ijzendoorn, 1999; Ehri *et al.*, 2000; Lonigan *et al.*, 2008a, b). The most recent meta-analysis (Lonigan *et al.*, 2008a, b), includes 83 well-controlled intervention studies (RCTs or quasi experiments with a control group and a pre-test–post-test design). The studies reviewed aimed to develop phonological awareness, alphabet

knowledge, and early decoding skills in unselected children and children with learning disorders in kindergarten or preschool. Virtually all of the studies had interventions that included some form of phonological awareness training delivered either individually or in small groups. This training taught children to identify phonemes in words (i.e., to match words with the same initial sound) or to manipulate phonemes in words (i.e., combine sounds to form spoken words or segment or delete parts of spoken words) and was typically combined with phonic reading instruction (training letter knowledge and training children to relate the letters in printed words to the sounds they represent). The intervention programmes were typically given in addition to any instruction children were already receiving, and usually the control group was untreated (i.e., they received whatever was typical teaching in their preschool or kindergarten). The meta-analysis showed that these interventions produced large improvements in phonological awareness ($d = 0.82$, that is, children who received an intervention targeting phonology improved by 0.82 of a standard deviation more on measures of phonological awareness than the control children). Importantly, word reading also improved more in the intervention than the control children ($d = 0.42$) as did spelling ($d = 0.61$).

It should also be noted that a recent meta-analysis focusing exclusively on children and adults with reading difficulties showed that phonic reading instruction (teaching that focusses on getting children to understand letter-sound rules) with or without phonological awareness training had positive effects on word reading accuracy ($d = 0.47$) and word reading fluency ($d = 0.51$; McArthur *et al.*, 2012). Similarly, another recent meta-analysis (Coleman *et al.*, 2013) examining interventions targeting phonology and phonic reading instruction in children with language disorders produced moderate to large improvements ($d = 0.45$ – 2.91) on measures of word reading and spelling. In summary, we can conclude that interventions targeting phonology along with letter-sound training and phonic reading instruction have clear and positive effects on children’s reading, spelling, and phonological skills. This conclusion is also consistent with earlier meta-analyses (Bus & van Ijzendoorn, 1999; Ehri *et al.*, 2000).

Moderators of outcome

Lonigan *et al.* (2008a, b) examined a large range of moderators that may help to explain variations in the size of intervention effects across the studies included in their meta-analysis. There was no evidence that the size of the effect was dependent on age or developmental level of the children or how the study was designed, nor were there any significant differences in effects between the different interventions. However, there were large differences between the interventions used, making it difficult to detect systematic variations in their effectiveness. Nevertheless, the results suggest that the best intervention effects are likely to be achieved when phonological awareness training is combined with teaching related to letter knowledge or phonically based reading instruction. Moreover, notably, phonological awareness

training appeared to be more effective when focusing on smaller units in speech such as phonemes (say the sounds in the word CAT -> /k/ /ae/ /t/) rather than larger units such as rimes (a rime unit is the part of a spoken syllable that follows the initial consonant (if there is one); so the rime unit in CAT is /at/) or syllables (Melby-Lervag *et al.*, 2012).

Interventions targeting reading fluency

Meta-analyses of outcome studies

In older children with dyslexia, basic word-level decoding skills may be mastered, but reading often remains dysfluent (slow and labored). Poor reading fluency can be a significant impediment to success in formal education. In a meta-analysis, Samuels *et al.* (2000) summarized the effects of interventions designed to remediate problems with reading fluency. These interventions all involved some form of guided repeated oral reading, which involves pupils reading and re-reading a text repeatedly, until a pre-specified level of proficiency has been met. The meta-analysis included studies where a training group had received a repeated reading intervention, with an untreated control group. Studies had to have pre-test and post-test measures of reading that were not based on the material used for training. Sixteen studies were included with children ranging in age from Grades 2 to 9 (6 to 13 years) and with both normally achieving children and children with reading difficulties. The results showed moderate effects from repeated reading on the different reading outcomes (decoding fluency $d = 0.44$, word recognition $d = 0.55$ and reading comprehension $d = 0.35$). The small number of studies did not allow for a conventional moderator analysis. The results from Samuels *et al.* (2000) were supported by those from another meta-analysis by Therrien (2004) that found substantial effects of repeated reading practice on measures of reading fluency ($d = 0.83$) and comprehension ($d = 0.67$). However, there are very few well-designed studies of repeated reading practice and both these meta-analyses included studies that had poor designs. We badly need more evidence concerning the effectiveness of repeated reading practice and other possible interventions to help remediate problems of reading fluency.

Recent studies targeting phonology and decoding

A number of recent studies were not included in the meta-analyses summarized earlier. Wollf (2011) studied the effects of a phonics-based reading intervention programme in 9-year-old Swedish children. The children ($n = 112$) were randomly assigned to either an intervention or a control group and received one-to-one tutoring for 12 weeks for a total of 40 hours. About 60% of the intervention time was spent on phonemic awareness training (learning to segment and manipulate the constituent phonemes in spoken words) and decoding (practising reading words and non words aloud, by sequentially "sounding out" unfamiliar words if necessary), with the rest of the time being spent on comprehension strategies and fluency

training. The results showed immediate improvements after intervention in spelling ($d = 0.30$), reading comprehension ($d = 0.41$), reading speed ($d = 0.15$) and phoneme awareness ($d = 0.43$). At follow-up a year later, significant effects on spelling and reading comprehension remained. The follow-up effects were mediated by the effects on phoneme awareness immediately after the intervention (supporting the finding of Hulme *et al.*, 2012).

Bowyer-Crane *et al.* (2008) reported a randomized trial that compared the efficacy of a phonology with reading intervention and an oral language intervention in children selected for poor language skills ($n = 152$). The children were just under 5 years old at the beginning of the study. The phonology with reading intervention involved training in letter-sound knowledge, phonological awareness (including articulatory awareness) and reading books at the instructional level. Direct teaching in sight word recognition was also included in order to build up children's reading vocabulary. The oral language intervention programme included direct instruction to develop vocabulary, inferencing, expressive language, and listening skills. Both programmes were delivered by specially trained teaching assistants working in the children's schools. Teaching sessions alternated between individual and small group lessons on different days. After 20 weeks of intervention, children in the phonology with reading group showed an advantage over the oral language group on literacy and phonological measures ($d = 0.4$ for decoding accuracy; $d = 0.4$ for spelling accuracy and $d = 0.7$ for phoneme blending (the examiner says a sequence of sounds and the child has to produce the target word (/k/ /ae/ /t/ -> "cat") and segmentation (the examiner says a word and the child has to break it into its constituent sounds CAT -> /k/ /ae/ /t/)). By contrast, children in the oral language group showed an advantage over the phonology with reading group on measures of vocabulary and grammatical skills. These gains were maintained over a 5-month period after the intervention had ceased.

Finally, Vadasy and Sanders (2010) reported a randomized trial evaluating the effects of phonics based instruction in a group of kindergarten children who performed in the bottom half of their class on measures of phonological awareness and letter knowledge. The intervention consisted of individual instruction in phonics, phonemic awareness, early decoding, and spelling skills for 30 min a day, 4 times per week for 18 weeks. The intervention produced improvements in phonological awareness ($d = 0.29$) and word decoding ($d = 1.27$) in the intervention group immediately after training.

Summary: interventions for decoding and reading fluency problems

Interventions for children who have decoding problems are well developed and there is now strong evidence from many randomized trials that teaching that targets phoneme awareness and letter-sound knowledge, in the context of structured phonic teaching, is highly effective in improving decoding skills.

There is less evidence concerning interventions for the reading fluency problems that often persist after basic decoding skills are mastered in children with dyslexia. Nevertheless, there is suggestive evidence that repeated oral reading programmes can help to improve reading fluency, although such interventions may be least effective for the children who need them most. Clinically, it is widely believed that maintaining an interest in reading and ensuring that children with dyslexia engage in frequent reading practice are important for helping to reduce the reading fluency problems that are a persistent problem in this group of children.

Reading comprehension impairment

Nature and causes of reading comprehension impairment

Children with reading comprehension impairment decode words accurately, but have problems understanding the meaning of texts that they can read (Hulme & Snowling, 2009, 2011). Such children may often go unnoticed in school because they read aloud normally. These children have been much less studied than children with dyslexia (see Chapter 53 for a detailed account).

Reading comprehension impairment is typically diagnosed if a child shows a large (at least 1 SD) discrepancy between reading accuracy and reading comprehension on a well standardized test, coupled with a reading comprehension standard score of 90 or below. In a recent standardization of a reading test involving a nationally representative sample of 1324 UK primary-school children, 3.3% of the sample met these diagnostic criteria (Hulme & Snowling, 2011).

A great deal of evidence points to the conclusion that the cause of reading comprehension problems is a broader language comprehension deficit (Hulme & Snowling, 2011). This theoretical position leads directly to the view that interventions targeting language comprehension skills are likely to ameliorate these children's reading comprehension difficulties.

Interventions targeting reading comprehension impairment

Meta-analyses of outcome studies

Several different meta-analyses have been published examining interventions to improve children's reading comprehension (Stahl & Fairbanks, 1986; Edmonds *et al.*, 2009; Elleman *et al.*, 2009; Swanson *et al.*, 2011). The most recent by Elleman *et al.* (2009) examines effects from interventions that target language comprehension skills. Studies in this meta-analysis had to employ either a pre-test – post-test control group design, post-test control with randomization, or a pre-test – post-test within subjects design using counterbalanced conditions. The studies included both unselected groups of children as well as children with learning disorders from pre-kindergarten to grade 12 (ages roughly 4 to 16 years) with English as their first language. The interventions all involved instructional methods

that aimed to increase word knowledge or reading comprehension that could be implemented in a classroom setting. Results showed that on reading comprehension tests that contained the words that were trained the mean effect size was moderate ($d = 0.50$, $k = 23$ groups). However, when effects were measured on standardized reading comprehension tests, effects were small ($d = 0.10$, $k = 16$). Notably, this meta-analysis included studies with short training durations (number of treatment hours ranging from 1–37.5), and this perhaps reduces the likelihood of effects on standardized measures. Nevertheless, the benefits from the interventions summarized by Elleman *et al.* are small in magnitude and arguably unlikely to be of clinical or educational importance.

Moderators of outcome

The moderator analyses in the study by Elleman *et al.* (2009) showed that when considering only custom measures and controlling for method variables, students with reading disabilities benefited more than three times as much as students without reading problems from the interventions. There were no overall differences between different teaching methods.

Recent studies targeting reading comprehension impairments

In a randomized trial, Clarke *et al.* (2010) examined the effects from three interventions designed to enhance reading comprehension in 8–9 year old children with reading comprehension problems ($n = 160$); text comprehension training, oral language training and text comprehension and oral language training combined. The two basic interventions (text comprehension training and oral language training) had very different characteristics. Text comprehension training involved working with children's reading books and involved teaching a range of strategies such as visualizing what was being conveyed in a text or making inferences from a text. The oral language training on the other hand involved working exclusively with spoken language. Children were taught the meanings of words they did not know, practised listening to stories and answering questions about their meanings and also practised generating their own narratives (stories) from sets of pictures. Children in this intervention also received instruction in understanding the figurative (nonliteral) use of language, such as learning the meaning of riddles and jokes. The combined intervention programme involved the key elements from both the text comprehension and oral language training programmes, which were combined to form an integrated instructional package. The interventions lasted for 20 weeks, with three 30-min (individual and small group) sessions per week. Compared with an untreated control group, all groups made significant and moderate to large gains on standardized tests of reading comprehension at post-test (for WIAT II $d = 0.59$ for text comprehension training, $d = 0.69$ for oral language training and $d = 0.99$ for text comprehension and oral language combined). Thus, in contrast to the meta-analysis by Elleman *et al.* (2009), large effects were demonstrated on

standardized measures. Although all groups maintained effects at follow-up 11 months later, gains were greater in the oral language group ($d = 1.24$ on WIAT II) than the other groups. Both the oral language and the combined groups demonstrated significant improvements in expressive vocabulary and this was a mediator of their improved reading comprehension.

Cantrell *et al.* (2010) examined the effects from a reading comprehension strategy programme in a randomized trial with 6th and 9th graders (approximate ages 10 and 13 years respectively). Students were taught strategies of word identification, visual imagery, self-questioning, paraphrasing and sentence writing. After a year of intervention (50–60 min a day), 6th graders ($n = 131$) receiving the intervention performed better than the control group ($n = 171$) on a standardized measure of reading comprehension, but the effect size was small (estimated effect size $d = 0.22$). For the 9th graders ($n = 353$), there was no significant improvement and the effect size was very small (estimated $d = 0.1$).

The difference in results between the Clarke *et al.* study and the Cantrell *et al.* study are difficult to explain. The participants in the Cantrell *et al.* study were older and possibly had more severe reading problems. It also appears that the group reading test used for selecting children for the Cantrell trial (the Group Reading and Diagnostic Evaluation) places heavy emphasis on reading accuracy as well as comprehension skills, so there is no evidence that the children in the trial had specific problems in comprehension that were out of line with their decoding skills. Overall the results from the Cantrell *et al.* study are clearly disappointing especially in relation to the amount of intervention received (roughly 1 hour per day for 1 school year). The results from the Clarke *et al.* study, which involved considerably less teaching time and produced larger effects on reading comprehension, suggests that targeting oral language skills in children with reading comprehension impairment may be particularly important.

Finally, it is worth noting that Fricke *et al.* (2013) reported a randomized trial examining the effects of an oral language intervention delivered to children who represented roughly the bottom 30% of children in nursery classes in terms of their oral language proficiency. The intervention started in the last term of nursery school and continued through the first two terms of reception class (a total of 30 weeks of intervention). Children in the intervention group showed significantly better reading comprehension scores ($d = 0.52$) at a 6-month delayed follow-up test. This effect was completely mediated by changes in language comprehension scores obtained at the end of the intervention. This study therefore replicates, with a younger sample, the effects found by Clarke *et al.* (2010) that oral language intervention can be a highly effective means of improving children's reading comprehension skills.

Summary: interventions for reading comprehension impairment

There are many fewer studies of interventions for reading comprehension impairment than for dyslexia. The assessment of

reading comprehension skills is inherently much more complex than the assessment of reading accuracy, as are the teaching methods required for improving reading comprehension. Current evidence nevertheless suggests that this disorder reflects an underlying weakness in oral language comprehension abilities and that interventions targeting oral language comprehension skills can be highly effective for improving children's reading comprehension skills. The interventions with the largest effects here (Clarke *et al.*, 2010; Fricke *et al.*, 2013) have involved teaching individual children, or children in small groups, over roughly four sessions a week for between 20 and 30 weeks in school. It should be emphasized that the children in these trials could all be considered to have significant educational weaknesses but the majority would not be viewed as having clinically severe language problems. Moreover, it should be emphasized that many children with language and reading difficulties would be likely to benefit from longer lasting interventions than the 20 to 30 week interventions that were delivered in these research studies. Further work in this area is badly needed. We need large scale trials of adequate duration that seek to establish generalized effects to standardized tests of reading and language comprehension.

Specific language impairment

Nature and causes of specific language impairment

Specific language impairment (SLI) has traditionally been defined as oral language skills that are much poorer than expected from a child's non verbal abilities and where other known causes (such as deafness) have been excluded (Bishop & Snowling, 2004). As in the case of dyslexia, however, there has been much controversy about the use of a discrepancy definition for this disorder and DSM-5 has now abandoned the use of such a definition. SLI, or more simply language impairment (LI) is thought to arise from deficits in both phonological and broader oral language skills (Bishop & Snowling, 2004) whereas dyslexia, in contrast, reflects a circumscribed difficulty with the phonological aspects of language.

Specific language impairment appears to be a relatively common disorder. In a large epidemiological study, Tomblin *et al.* (1997) examined a stratified cluster kindergarten sample ($n = 7218$) with a language screening test. The children who failed the screening were given a further diagnostic battery of tests. The diagnosis of SLI required normal hearing and non verbal IQ and a score of 1.25 SD below the mean for the child's age on two out of five language tests. Results showed an overall prevalence for SLI of 7.4%, with 8% for boys and 6% for girls. However, it should be noted that there are high levels of comorbidity between SLI, dyslexia, speech disorders, motor coordination disorder, general learning disorders, and ADHD (Beitchman *et al.*, 1990; Botting, 2005; Pennington, 2009; see Chapter 3), which may lead some to question the use of the term "specific" in relation to this disorder.

The causes of SLI remain poorly understood. Descriptively, children with SLI appear to have pronounced problems in word learning (vocabulary knowledge), grammar learning and phonology. In practice, the major approaches to intervention target different aspects of these children's language learning weaknesses head on in a direct and highly structured way. The interventions evaluated in this section generally include children with significant language learning weaknesses without imposing any restrictive diagnostic criteria for including children who require intervention.

Interventions targeting specific language impairment

Meta-analyses of outcome studies

Given that word learning is a major area of difficulty for children with SLI, interventions focusing on direct vocabulary instruction are relevant to treating the disorder as are interventions involving joint book reading, which help to improve oral language skills (for interventions related to phonology refer the earlier section on dyslexia). Several meta-analyses of the effects from such interventions have been published.

Elleman *et al.* (2009) analyzed effects from interventions implemented in classroom settings that aimed to increase word knowledge or comprehension. The studies included had to employ either a pre-test–post-test control group design, post-test control with randomization or pre-test–post-test within subjects design using counterbalanced conditions. The samples were first language learners from pre-kindergarten (approximate age 3–4 years) to grade 12 (approximate age 16 years) both with and without learning disorders. Results showed that effects from interventions were small to moderate when vocabulary was measured with standardized measures ($d = 0.29$, $k = 14$) and large when vocabulary was measured with tests constructed to assess knowledge of words directly taught in the study ($d = 0.79$, $k = 18$). In this analysis, effect size was correlated with control group strength and effect sizes were smaller for randomized trials: both of these findings suggest that the overall effect sizes reported overestimate the “true” effects of the interventions evaluated. Higher levels of discussion were associated with larger effect sizes.

A second line of research relevant to enhancing language comprehension and word learning involves studies of joint book reading. In joint book reading, a child and an adult take turns to read aloud from the same book and the adult engages the child in discussion about the passage being read. Lonigan *et al.* (2008a, b) evaluated the effects from studies of shared book reading interventions (represented by change in frequency or in the style of shared reading activities), implemented either by parents or in school settings. Studies had to use a randomized experiment or a quasi-experiment that was not seriously confounded. The results showed a large effect of shared book reading on measures of oral language ($d = 0.73$, $d = 0.57$ with

outlier excluded, $k = 16$). In this study, there were no differences between older and younger children, no differences between at risk and not at risk children and no difference between parent or teacher delivered interventions. Moderate to large effects from joint book reading interventions were also found in a meta-analysis by Mol *et al.* (2009).

Recent studies targeting language comprehension

In a cluster randomized trial, Neuman *et al.* (2011) examined whether helping Headstart preschoolers ($n = 604$) to learn words through categorization could enhance new word learning. The intervention program was organized on topics that represented different taxonomies of constructs. The children received the intervention for 12–15 min each day in addition to their regular teaching. Overall, results showed a small effect from the intervention immediately after training ($d = 0.07$) on a standardized vocabulary test (W-J picture vocabulary test). There were, however, larger effects on a custom measure of word knowledge, based on words that were used in the study.

Tuckwiller *et al.* (2010) used a regression discontinuity design to examine the effect of vocabulary instruction on kindergarten children (children were selected to be given intervention based on low scores at pre-test on the PPVT IV). The vocabulary instruction was based on a storybook with just 4 target words taught to children in small groups over 2 days. At post-test measures of children's ability to give meanings for these four words showed small to moderate improvements ($d = 0.33$), and the effect lasted on a delayed post-test. The very limited amount of intervention delivered here, the small number of words taught, and the fact that these children were from a typically developing population, greatly limits any conclusions that can be drawn from this study for clinical practice.

Bowyer-Crane *et al.* (2008) identified children at school entry with poorly developed oral language skills and provided them with either an oral language intervention focusing on vocabulary and narrative skills, or a phonology with reading intervention focusing on letter-sound knowledge, phonological awareness, and book reading. Both interventions were delivered by specially trained and supported teaching assistants working in the children's schools, using two scripted interventions. The intervention sessions alternated between small group and individual teaching sessions, over a period of two school terms (20 weeks). The oral language intervention, in comparison to the phonology with reading intervention, produced improvements in specifically taught vocabulary ($d = 1.00$) and expressive grammatical skills ($d = 0.31$).

In a similar study, Fricke *et al.* (2013) reported a randomized trial examining the effects of an oral language intervention delivered to children starting in the last term of nursery school (age 4 years) and continuing through the first two terms of reception class. Children in the intervention group showed significantly better performance ($d = 0.8$) on a latent oral language

factor (defined by measures of vocabulary, listening comprehension, and expressive language) as well as on a latent spoken narrative factor ($d = 0.38$). Both effects were maintained at a 6-month delayed follow-up test.

Summary: interventions for oral language impairments in children

Current evidence suggests that structured language intervention programs that involve teaching vocabulary, listening comprehension and narrative skills are effective in improving oral language skills in the early years of formal schooling. The effect sizes from such interventions are moderate to large. Most of these studies, however, have arguably involved children whose language difficulties are not particularly severe, and we have little evidence about the effectiveness of interventions for children with severe oral language difficulties. More studies with such populations are badly needed.

Mathematics disorder

Nature and causes of mathematics disorder (see Chapter 53)

There have been great advances in research on mathematical development and performance in the last two decades. However, compared with studies of reading and its disorders, where we now have extensive knowledge about their causes and treatment, much work is still to be carried out in the field of mathematical skills and mathematics disorder. The diagnostic criteria for mathematics disorder in DSM-IV (American Psychiatric Association, 1994), was based on a discrepancy definition in which mathematics abilities as measured by a standardized test, needs to be substantially below the expected given chronological age, measured intelligence, and age appropriate education. However, in DSM-5 mathematics disorder is conflated with other forms of difficulty under the rubric of specific learning disorders and a discrepancy definition is not adhered to (this appears unfortunate—see Chapter 53).

Mathematics disorder, like other disorders considered in this chapter, is also relatively common. Lewis *et al.* (1994) assessed reading, arithmetic and non verbal ability in all 9- and 10-year old children in a single school district in the UK. Using a cutoff of a mathematics standard score of 85 or less coupled with normal non verbal ability (at or above a standard score of 90), some 3.6% of children were classified as having mathematics disorder (of these children roughly two thirds also had a reading disorder diagnosed in an analogous way).

In relation to theories of the causes of mathematics disorder, the main discussion in the field has been whether the core deficit is in an abstract approximate number sense system (Dehaene,

1997; Butterworth *et al.*, 2011) or whether it is the result of a more general deficit in working memory or visuo spatial abilities (e.g., Geary, 2004) or perhaps a verbally based deficit that involves problems in learning counting skills (Hulme & Snowling, 2009; see Chapter 53). Arguably, to date there has been little linkage between debates about the causes of mathematics disorder and interventions for these children.

Interventions targeting mathematics abilities

Meta-analyses of treatment studies

There has been an increase in the number of intervention studies for mathematics disorder in the last 10 years. A meta-analysis by Gersten *et al.* (2009) examined interventions for mathematics targeted toward children with identified learning disorders. To be included studies had to evaluate the effectiveness of a well-defined method for improving mathematics proficiency and be randomized controlled trials or quasi experiments where participants were matched on pre-test data. Large effects were obtained for interventions that contained explicit instruction in specific mathematic skills ($d = 1.22$, $k = 11$), instruction in a general strategy for solving problems ($d = 1.56$, $k = 4$), teaching children verbalizations of reasoning (i.e., teaching children to give explicit verbal descriptions of the reasoning processes used to solve problems; $d = 1.04$, $k = 8$) and using a specific sequence and range of examples ($d = 0.82$, $k = 9$). Moderate effects were demonstrated in interventions that focused on using visual representations for teacher and student ($d = 0.47$, $k = 12$). Studies with treated controls generated smaller effect sizes than untreated controls and studies using norm referenced tests showed smaller effect sizes than studies using researcher developed tests, all of these factors suggest that the effect sizes reported here may overestimate the “true” effects of the studies reviewed.

Recent studies targeting mathematical abilities

Klein *et al.* (2008) examined effects from a pre-kindergarten mathematics intervention in a randomized trial ($n = 278$). The intervention consisted of small group mathematics activities with concrete materials based on early numeracy skills, numerical operations, and logical reasoning for use both in educational settings and at home. Total intervention duration was 58 small group sessions of 20 min. The intervention group achieved significantly greater gains on a broad test of arithmetic skills (Child Math Assessment) than the control group ($d = 0.50$).

Clements and Sarama (2008) reported a clustered randomized trial of their “Building Blocks” pre-school mathematics programme. Groups of children in 36 pre-school classrooms (276 children) were assigned to receive the Building Blocks curriculum, which involved small group as well as individual and whole class instruction designed to improve children's counting and early number skills, or to receive an alternative

preschool mathematics curriculum or to an untreated control. All programmes were implemented over 26 weeks. The children who received the Building Blocks programme showed significant improvements in early mathematical skills (assessed by the Early Mathematics Assessment of children's mathematical knowledge) compared to the untreated control children ($d = 1.07$) or those given an alternative preschool mathematics curriculum ($d = 0.47$). A follow-up study of the Building Blocks programme (Clements *et al.*, 2011) used a cluster randomized trial ($n = 1375$ children in 106 classrooms) and showed a sizeable benefit from the intervention at post-test on children's mathematical understanding ($d = 0.72$).

In the United Kingdom, Torgerson *et al.* (2010) reported the results of a randomized trial evaluating the efficacy of a school-based intervention for 6–7 year old children with poor mathematical skills. The intervention, Numbers Count, is a 12 week programme, consisting of daily 30 min one-to-one sessions, delivered by specially trained teachers. Teaching in the programme uses shape, space measures and handling data as contexts for the development and application of children's number skills. The programme is scripted, but individualized, with teachers identifying teaching points based on continuing assessments of a child's mathematical skills. In the trial, 144 children who received the Numbers Count intervention showed reliably higher scores immediately after the intervention had finished on a standardized test of mathematical ability ($d = 0.33$) compared with a waiting list control group ($N = 274$).

Finally, in a small scale experimental study Ramani and Siegler (2008) randomly assigned 124 young children (aged 5.4 years) from low income backgrounds to two experimental conditions. One group played a linear board game involving counting. Here consecutive squares on the board were labeled with the numerals 1–10 and to advance children turned a spinner that was labeled with the numerals 1 or 2 on its two sides. The other group played a similar game in which squares were simply colored and the spinner had two different colors on it. The children played the game for just four 15–20 min sessions over 2 weeks. The children in the experimental group showed advantages over the control group on measures of numerical magnitude comparison, number line estimation, counting and numeral identification, which remained 9 weeks after the intervention (effect sizes were moderate to large). This study suggests that practice in counting can have beneficial effects on early arithmetic development in children from disadvantaged backgrounds.

Summary of interventions for mathematical abilities

There are relatively few well controlled studies of interventions for mathematical abilities. However, two published programmes (Building Blocks (for pre-school children) and Numbers Count (for 6–7 year old children)) have reasonable evidence for their efficacy.

The effectiveness of educational interventions for children with general learning difficulties

So far in this chapter, we have concentrated on interventions for children with specific learning difficulties. There have been a number of experimental and quasi-experimental studies that have evaluated the effectiveness of interventions for children with general learning difficulties (intellectual disabilities in US terminology); all of these studies concentrate on reading (or reading and language) skills.

Allor *et al.* (2010a, b) evaluated the effectiveness of a phonic reading programme with 28 children with moderate intellectual disabilities (IQs 40–79). Children were randomly assigned to daily small group reading instruction or “typical special education” ($N = 16$ intervention, $N = 12$ control). The programme was delivered for between 1 and 1.5 years and produced medium to large effect sizes on a standardized measure, the Test Of Word Reading Efficiency (TOWRE $d = 0.72$) and non word reading efficiency (TOWRE $d = 1.00$); these tests simply assess how many words or non words a child can read aloud in 90 s.

In a similar study with a larger sample, Allor *et al.* (2010a, b) evaluated the effectiveness of a comprehensive reading programme that involved teaching phonological and phonemic awareness, oral language skills, letter knowledge, word reading, vocabulary, reading fluency and comprehension. Fifty-nine children with moderate intellectual disabilities (IQs 40–79) were randomly assigned to either the treatment or a business as usual control group. Teaching for the intervention children was delivered in daily small group sessions across 2 to 3 school years. The intervention group showed greater gains, with small to moderate effect sizes, on measures of phoneme awareness ($d's = 0.53$ to 0.66) non word reading ($d's = 0.49$ to 0.58) and word reading ($d's = 0.26$ to 0.51).

In another small-scale RCT Finnegan (2012) investigated methods of teaching reading to children with intellectual disabilities. Here 52 children (mean age 8.6 years; mean IQ where available 56) were randomly assigned to three groups: synthetic phonics, an analogy-based phonic reading programme, or an untreated control. The synthetic phonics programme involved teaching children to “sound out” unknown words on a letter by letter basis and blend the sounds together to form the word. The analogy-based phonics programme focussed on larger segments of spoken words when trying to decode them (for example, given the word HAT the child might be asked to think of other words that share the same ending (CAT, SAT) or the same initial letter (HIT, HIS) and work out from this the pronunciation of HAT). Teaching only involved 12 sessions. Both phonics programmes resulted in improvements compared to the control group for children's ability to read words taught in the programme ($d = 0.54$ and 0.52) and on a measure of

transfer to untaught words there was also an advantage for the synthetic phonics group compared to the control group ($d=0.33$). Clearly, this study has low power but suggests that phonic reading instruction can be beneficial for children with general intellectual disability.

Burgoyne *et al.* (2012) reported a randomized trial evaluating the effects of an integrated reading and language intervention programme for children with Down Syndrome. The intervention involved a highly structured phonic reading programme (comparable to that used by Bowyer-Crane *et al.*, 2008) coupled with vocabulary instruction and was delivered by teaching assistants in 40 min sessions on each school day over 20-weeks. After 20 weeks of teaching, the intervention group ($N=28$) showed significantly greater progress than the waiting control group ($N=26$) (with small to medium to small effect sizes) on measures of single word reading ($d=0.23$), letter-sound knowledge ($d=0.42$), phoneme blending ($d=0.54$) and knowledge of words meanings taught in the programme ($d=0.47$). However, there was no statistically reliable generalization to skills not directly taught (non word reading, spelling, standardized expressive and receptive vocabulary, expressive information, and grammar).

Summary

These studies of children with general learning difficulties are typically small scale, and hence suffer from limited statistical power, nevertheless the results are consistent in suggesting that reading accuracy problems in this population can be ameliorated by phonically based reading instruction coupled with phonological (phonemic) awareness training. In short, the same approach to teaching reading to children with dyslexia appears to be effective for children with general learning difficulties also.

The effectiveness of interventions targeting general cognitive functions

In recent years, strong claims have been made for interventions that aim to enhance language and reading skills by training more general cognitive capacities (e.g., Merzenich & Jenkins, 1998; Klingberg, 2010). One such category of interventions aims to train working memory capacity, a cognitive system that has been observed as providing an all-purpose "work-space" for diverse cognitive functions such as reading, language, maths, and general attentional abilities. It has been claimed that working memory impairment is a contributory cause to many different forms of learning difficulty including language impairment, dyslexia, reading comprehension impairment, mathematics disorder, and attention deficits (Melby-Lervåg & Hulme, 2012; Melby-Lervåg *et al.*, 2012). According to such a theory, if working memory capacity can be increased

through training, this would have diverse effects on people's ability to perform cognitive tasks, such reading and language comprehension, arithmetic and reasoning.

In the last decade, a number of studies have examined the effects from working memory training. In a meta-analysis, Melby-Lervåg and Hulme (2012) summarized the effects from such training in studies that used a design with a pre-test and post-test and a control group (both randomized and non randomized studies, and studies with both trained and untrained control groups). Twenty-three studies with 30 group comparisons met the criteria for inclusion. The studies involved clinical samples and samples of typically developing children and adults. Meta-analyses showed that the working memory programmes produced reliable short-term improvements in working memory skills. However, there was no convincing evidence of generalization from working memory training to other skills (non verbal and verbal ability, inhibitory processes in attention, word decoding and arithmetic). These programs appear to produce short-term, specific training effects that do not generalize to skills that are important for children with learning difficulties. Moreover, this pattern been confirmed in a recent well controlled study with adults (Redick *et al.*, 2012) and for the Cogmed training program in a further meta-analysis (Hulme & Melby-Lervåg, 2012).

A second category of interventions based on an approach that seeks to train general cognitive skills derives from a theory that language and literacy learning difficulties in children arise from problems related to rapid auditory temporal processing (Tallal, 2004). According to this theory, a basic deficit in perceiving rapidly changing auditory signals results in problems in perceiving speech which in turn lead to language learning difficulties. It has been claimed that neuroplasticity means that training of auditory processing skills can lead to improvements in underlying neural systems and thereby ameliorate children's language and reading problems (Merzenich & Jenkins, 1998). One such training program is called Fast ForWord which is marketed by the Scientific Learning Corporation in the US. In this program, children are trained with computer modified speech in which critical cues in speech are slowed down in order to make them more discriminable to children with auditory temporal processing impairments. In a meta-analysis by Strong *et al.* (2011) the effects of the Fast ForWord training programmes were examined. Six studies that met the inclusion criteria of randomized controlled trials or matched group comparison studies with baseline equivalence published in refereed journals were found. The results showed that there was no significant effect of Fast ForWord on language and reading measures when the training groups were compared with active or untreated control groups. Thus, Fast ForWord cannot be recommended for treating language and reading problems.

Conclusions and future directions for clinical practice and research

We have considered evidence for the efficacy of educational interventions for reading disorders (dyslexia and reading comprehension impairment), language disorders and mathematics disorder. It is clear that research on dyslexia is most advanced and we have good evidence that phonics reading instruction coupled with oral phoneme awareness training works relatively well as a way of reducing the severity of these children's reading problems. However, problems with spelling and reading fluency appear to be more difficult to remediate in this population. There is encouraging evidence that interventions for young children with weak oral language skills can be effective and that such interventions have knock on effects to improve reading comprehension skills. Work on interventions for mathematical difficulties is perhaps least advanced, but there is evidence for moderate effects for two published intervention programs.

It may be worth emphasizing some limitations to the evidence considered. First, nearly all the studies considered have fairly liberal criteria for including children to be treated and we have rather little evidence about the effectiveness of the interventions reviewed for children with severe difficulties. Second, nearly all the studies considered involve interventions of quite short duration with only short-term follow-up. A third issue that needs more evidence is the cost effectiveness of the interventions considered. However, given that a number of the interventions considered can be delivered by trained teaching assistants with small groups of children, it is likely that they could be considered potentially highly cost effective. Finally, it is notable that most intervention studies focus on evaluating the direct effects that a given intervention has on a given area of educational attainment (reading, language, or maths skills). For interventions with demonstrated effectiveness on such measures, it would be useful to have longer-term studies that included broader outcome measures, since clinically it is often claimed that effective educational interventions can have quite broad effects on well-being and self-esteem.

CHAPTER 42

School-based mental health interventions

²Department of Psychological Medicine, Christchurch School of Medicine, University of Otago, Christchurch, New Zealand

Introduction

Ensuring that children with mental health needs receive effective care is challenging, and many who need care do not receive help (Burns *et al.*, 1995; Mariu *et al.*, 2012). Schools potentially provide a setting in which interventions can be delivered in an environment designed to meet the developmental needs of children and adolescents. While the primary purpose of schools is to provide education, poor mental health impacts adversely on educational outcomes and learning difficulties and mental health problems frequently co-exist, so that addressing mental health needs within the school setting is likely to lead to educational gains.

Schools are complex institutions that have the potential to exert a positive influence on behavior and academic attainment of students, regardless of their background (Rutter *et al.*, 1979). They can also increase risk for later mental health problems; the negative impact of bullying is clear (Jimenez Barbero *et al.*, 2012) and problematic teacher–pupil relationships are related to higher levels of psychiatric disorder in pupils at 3 year follow-up (Lang *et al.*, 2013).

Global school mental health

Schools vary in the way they address mental health problems, with socioeconomic status, geography, political stability, religion and culture all having an impact. There have been some global school mental health initiatives. The World Health Organization (WHO) developed a school mental health model incorporating mental health promotion, prevention, treatment and psycho-education (Hendren *et al.*, 1994). This led to initiatives such as the Health Promoting Schools approach, now applied in over 40 countries (Wei and Kutcher, 2012). The Education for All movement developed by UNESCO has included initiatives to address mental health and emotional support and to ensure that the school environment is supportive by preventing bullying, violence and by promoting good interpersonal

relationships and teaching life skills. The International Alliance for Child and Adolescent Mental Health and Schools, a relatively new initiative involving over 35 countries, aims to promote the mental health and well-being of children and young people.

There have been a number of countrywide initiatives, such as the Social and Emotional Aspects of Learning initiative in the United Kingdom and the European Network of Health Promoting Schools, which has 40 different member nations.

These initiatives tend to be taken up by high income countries with middle and low income countries lagging well behind. To address this disparity, a Child Mental Health Awareness Task Force was set up by the World Psychiatric Association, the WHO and the International Association for Child and Adolescent Psychiatry and Allied Professions. A mental health education resource was developed and introduced in nine countries. The impact is not known but this initiative has provided valuable information about the feasibility of developing and implementing school mental health programs in diverse settings (Wei & Kutcher, 2012).

Addressing mental health problems at schools

School-based services should be considered in the wider context of the family, the health system and other community resources. In an ideal world, services should be delivered in collaboration with a coherent over-arching framework, but in practice services are often delivered in parallel, or not at all. Working toward a more organized system would be of value in most parts of the world (Weisz *et al.*, 2005).

The role of the school differs according to the prevalence of disorder, the extent and nature of the resultant disability and the impact on the functioning of the class or school. For disorders with *high prevalence* rates, such as disruptive behavior disorders, consideration should be given to management within the school

setting, using whole school, whole class, or indicated programs. For *lower prevalence* disorders, which affect the ability of the individual student to function at school, such as autistic spectrum disorders (ASDs), individual interventions may be needed to support individual students. Individuals with mental health problems are often stigmatized, even by young school children. While there have been some school-based interventions to try and address this problem, evidence of their efficacy is insufficient to warrant their introduction (Schachter *et al.*, 2008).

Strengths and weaknesses of school-based interventions

In schools, preventive interventions can be provided to a large proportion of the target population and school clinics can potentially provide treatment conveniently and without the stigma inherent in attending a mental health service. Integration with specialist mental health services can be achieved by having a close liaison between staff in both settings. While this rationale is appealing, there are practical difficulties including competing demands on the time of teachers and their pupils and lack of attendance at school by some students with mental health difficulties. In some parts of the world, the provision of education is not universal, resources are limited and the provision of mental health care within schools a distant aim. Families play a vital role in the mental health of young people but involving them in school-based interventions can be challenging.

Identifying risk and disorder

Given the high rates of undetected and untreated mental health problems in children and adolescents, mental health screening at schools has been advocated (U.S. Department of Education Office of Special Education and Rehabilitative Services, 2002; US Preventive Services Task Force, 2009). There are advantages of broad access to young people and students may be more likely to attend interventions if they are in the school setting (Levitt *et al.*, 2007). However, there has been some opposition to school-based screening because of potential stigmatization, limitations of screening instruments, and potential difficulties around consent (National Research Council and Institute of Medicine, 2009). The evidence that screening can lead to improved outcomes is limited. For example, there is evidence to support screening for the identification of depressive disorder in adolescents (but not children) but no evidence to show that this has resulted in improved mental health outcomes, or in increased uptake of services (Williams *et al.*, 2009).

Given the complex nature of screening in schools, the cost and benefits of screening should be carefully weighed up after considering the following:

- Evidence that screening results in improved outcomes;
- The availability of validated screening tools of adequate sensitivity and specificity;
- The acceptability of screening to young people and school staff;

- The potential for stigmatization of identified youth;
- The provision of information about the purpose, risks and benefits of screening;
- Consent processes;
- The availability of the resources and skills to confirm screening results, assess risk and clarify the need for intervention;
- The development of pathways for prevention and intervention following screening; and
- The availability and cost of subsequent intervention.

Methods of delivering interventions at school

Mental health interventions may be delivered in schools in a number of ways. Generally health promotion interventions are delivered to the *whole school* to try to create a positive school climate, which promotes mental health and pro-social behavior. These may integrate interventions for parents and the community. *Universal preventive interventions* are typically delivered to *whole classes*, or sub-groups of these classes, while *targeted* interventions can be delivered to groups *selected* because of a risk factor or where there are signs or symptoms *indicating* an incipient problem.

Some preventive interventions incorporate a stepped care approach to provide an *integrated range* of interventions, delivered universally with embedded systems to identify and intervene with students at elevated risk. There is evidence that school-based programs may be cost effective, for example, social and emotional learning programs have been estimated to save £84 for each pound invested, while programs to reduce bullying result in savings of £14 per pound invested (Campion, 2013).

There are different options for providing *treatment* for mental health problems within schools. Schools may provide specific settings for young people with specific needs: (i) through the provision of *special classes*, typically with low numbers of students and a high staff student ratio; and (ii) through *special schools*. Some schools have resident *school clinics* that may provide interventions for mental health problems. A recent meta-analysis of counseling and psychotherapy in schools showed the broad range of interventions delivered, but overall there was a small effect size, although this analysis was limited by the quality of the included studies (Baskin *et al.*, 2010). Mental health clinicians from specialist services may provide *consultation and liaison* services to schools. School staff may help ensure administration of medication, provide adjunctive support and work with mental health clinicians and the family to ensure an integrated approach to the difficulties faced by the young person.

A national survey of a representative sample of the 83,000 schools in the USA was carried out to determine the types of mental health problems presenting, the interventions delivered and wider issues of funding and administration of the services. Findings indicated that there was a recognition of the need to respond to mental health problems in schools and that services

were widely available, mostly comprising assessment, behavior management, crisis intervention, and counseling. Concerns over rising need and decreasing resources to address the need were raised. The authors identified a need for further research to explore the way in which these services are delivered, the adequacy of training of school personnel and the effectiveness of combinations of prevention and treatment in the services provided (Teich *et al.*, 2007).

In a large survey of 599 primary schools and 137 secondary schools carried out in the UK, two thirds of schools reported that they provided mental health interventions. These were mostly for those with symptoms and clear evidence of mental health problems and were aimed at treatment, not prevention. Of concern were reports that the interventions were mostly not based on evidence and training of teachers was limited (Vostanis *et al.*, 2013).

Staff delivering interventions

School-based guidance counselors deliver psychological support for large numbers of young people in schools and the ease of access and timeliness makes this a valuable resource (Pattison & Harris, 2006). The humanistic counseling model most often used, helps students resolve crises and improve mental health and emotional well-being (Cooper, 2013). In US schools, a review of 132 counseling and psychotherapy interventions found them to have a moderately beneficial effect (effect size [ES] = 0.44). Interventions for adolescents outperformed those for children, and although group and individual interventions were equally effective, single sex groups did better than mixed sex groups. Well-trained mental health professionals outperformed less well-trained staff (Baskin *et al.*, 2010).

There is evidence that *school-based social workers* have a positive impact on students' mental health with a small effect on conduct problems (ES = 0.23) and a moderate effect on anxiety and depression (ES = 0.4) (Franklin *et al.*, 2009).

Mental health work is a key part of the role of *school nurses* who also provide an important link between the school and outside agencies such as social services, special education and specialist child mental health services (Prymachuk *et al.*, 2012).

Teachers may provide interventions directly, for example, providing class-based behavioral management programs and individual students with specific needs may have support from *teacher aids*.

School psychologists, child psychiatrists, and other child mental health professionals may provide interventions to patients within school clinics and may support school staff to address the mental health needs of their students.

Types of intervention

Interventions provided at a school level to promote mental health may include educating staff about how to interact

positively with young people, ensuring that teachers are trained to develop positive and supportive relationships with their pupils and teaching teachers to manage difficult student behaviors. Interventions may be psycho-educational, delivered to whole classes as part of the syllabus, often as part of health education. Group interventions may be provided in schools for young people with mental health needs. Individual counseling may be provided and teacher aids may provide within-class interventions, for example, providing support for children with disruptive behavior. Some interventions may involve families, who may be invited to attend group sessions that are run in parallel with groups for students, or are stand-alone for parents only.

More recently, the use of technology has been considered. Interventions delivered through computers potentially offer some advantages over traditional implementation methods as they require less staff training and preparation time, guarantee consistency, provide flexibility in delivery, and, if well designed, can engage and maintain student interest and involvement. Mobile phones and tablets are likely to be used increasingly to deliver mental health interventions, although to date, phones are generally adjunctive to other interventions, and there is no evidence as yet, that an intervention delivered solely on mobile phones can prevent or treat mental health problems.

Programs developed for delivery at school

Programs targeting overall mental well-being

In addition to the development of cognitive and academic skills, schools are viewed as important settings for the fostering and development of social and emotional skills and a multitude of programs, based on social learning theory and cognitive behavioral approaches have been introduced as life skills programs. Social and emotional competencies include self-awareness, self-management, social awareness, goal setting, relationship skills and responsible decision making. Many programs teach specific skills, such as how to refuse drugs, alcohol or premature sexual behavior. A recent meta-analysis of social and emotional learning programs across the age-range of 6–16 years demonstrated initial moderate beneficial effects on social skills, pro-social behavior, positive self-image and academic achievement and reductions in antisocial behavior with initial small effects on reducing substance abuse and mental health problems (depression, anxiety and self-harm) (Sklad *et al.*, 2012). At 6 months follow up, there was a drop to a small effect in all areas, but within a population, these may be of public health benefit (Knapp *et al.*, 2011; Campion, 2013).

Problem behaviors and conduct disorder

Early behavioral difficulties are often evident in classroom settings from a young age and can herald developing conduct disorder but even when identified early, there is limited evidence about the effectiveness of classroom-based interventions in the prevention of conduct disorder. For schools with a high proportion of children at known risk of developing conduct

disorder, offering classroom-based emotional learning and problem-solving programs for children between 3 and 7 years of age has been recommended (NICE, 2013). Enhancing the skills of teachers using behavioural techniques shown to be effective for parents is a promising approach. Early evaluation of the Incredible Years Teacher Training Program has shown benefits for both teacher practices and child behavior but await replication (Baker-Henningham *et al.*, 2012).

The Good Behavior Game (GBG), is a widely utilized universal behavioral management intervention delivered by elementary teachers to reduce aggressive and disruptive behavior in the classroom and its effectiveness is currently being evaluated in several countries in large-scale trials (National Research Council and Institute of Medicine, 2009).

For classroom conduct problems in older children and adolescents, contingency behavioral management programs have been developed from social learning principles. Teachers use techniques such as giving clear instructions, planned ignoring, time-out and token reinforcement in class with children with disruptive or aggressive behavior. These programs achieve a moderate reduction in aggression, sustained to at least 12 months, in both primary and secondary school students (Mytton *et al.*, 2006; Matjasko *et al.*, 2012).

Programs with the strongest evidence include: Programme for Academic Skills, Contingencies for Learning Academic and Social Skills and Reprogramming Environmental Contingencies for Effective Social Skills (Blissett *et al.*, 2009).

In adolescence conduct problems often intensify with more severe and wide-ranging consequences. Thus multimodal treatment interventions targeting the school as well as home and the wider community have been developed. The Fast Track intervention targeted social cognitive skills, reading, and modification of the disruptive and rejecting classroom environment as well as home visiting, mentoring and parent behavior-management. Despite the intensity of this well-funded program, at long-term follow up a reduction in conduct disorder was only demonstrated for those at the highest risk and not for the intervention group as a whole (Conduct Problems Prevention Research Group, 2011).

Students whose behavior cannot be managed in a typical classroom may be placed in an alternate education setting. This is often the last attempt to intervene for students who are at increased risk of a range of negative outcomes over the life span. The most effective behavioral management strategies have been identified by clinical consensus (Tobin and Sprague, 2000) resulting in a comprehensive framework for preventing and responding to challenging behavior by building a predictable environment with structure and routine, and with reinforcement delivered contingent on the student displaying the desired behavior. However, a review of alternate education settings showed that while the recommended low student to teacher ratio in this framework was implemented, most did not use recommended behavioral strategies (Flower *et al.*, 2011).

Attention hyperactivity disorder (ADHD)

For children with attention hyperactivity disorder (ADHD), a comprehensive management plan that includes psychological and behavioral management at school as well as home has been recommended (NICE, 2008).

As teachers have limited training about mental health, in-service training sessions to increase teachers' knowledge about ADHD and practical ways to manage children with ADHD in the classroom have been developed. These include how to adapt lessons and structure the classroom environment to reduce distraction and how to implement behavioral management plans (Merrell, 2009). The importance of giving clear concise instructions, ensuring that tasks are broken down into small manageable steps, reinforcing desired behavior, planned ignoring and effectively managing undesirable behaviors is emphasized and reinforced with practice.

Behavioral management interventions by teachers result in moderate beneficial effects on behavior of children with ADHD (Fabiano *et al.*, 2009) with less robust evidence for effects on academic achievement or the core ADHD symptoms (DuPaul *et al.*, 2012). The dose or intensity of treatment, or the setting required to effect a meaningful change is not yet established, although there is some evidence from open studies and case reports that equivalent effects may be witnessed in special classes and general settings (DuPaul *et al.*, 2012). There are important gaps in the literature about the long-term effectiveness of classroom-based interventions, how best to sequence interventions and, as the current evidence comes mostly from primary schools, how these interventions might be implemented in the high school environment.

Computers have been used to assist the presentation of academic material (Rabiner *et al.*, 2010). Immediate and frequent feedback is given along with reinforcement and the highlighting of important information. Computer attention training (CAT) has been used as a training tool to decrease inattention (Steiner *et al.*, 2011) but the effectiveness of these technologies for children with ADHD requires further evaluation.

Although parents of adolescents with ADHD often report school difficulties as a primary concern, the evidence for strategies in this age group is inconclusive (Young and Amarasinghe, 2010). In practice, a pragmatic approach is usually taken to develop individualized interventions for students.

Substance use disorders

Early initiation into drug use is a risk factor for the development of substance abuse and the high cost of this disorder, both to the individual and to society, has led to the development of early intervention programs, delivered to increasingly younger students in schools. Many of these programs are generic for all substances and some target specific drugs.

Universal generic school-based preventive programs include education about the risks of drugs of abuse; skills training to address the social influence of peers and the media; and cognitive behavioral approaches to address the modeling and

reinforcement of substance use that children may have been exposed to. Susceptibility is increased by social vulnerability such as poor personal and social skills and some programs also address these difficulties. In addition, multi-modal programs combine curricular approaches with wider initiatives that may include programs for parents and communities.

Universal interventions that target substance abuse using social skills programs have been shown to be effective in increasing knowledge about drugs, decision-making skills and resistance to peer pressure and decreasing illicit drug use, although most did not have long-term follow-up (Faggiano *et al.*, 2005; Jackson *et al.*, 2012; Karki *et al.*, 2012; Teesson *et al.*, 2012; Norberg *et al.*, 2013).

Universal preventive programs: alcohol

Until recently, several systematic reviews concluded that classroom-based preventive education was not effective in reducing alcohol-related harm and the importance of restricting access and reducing alcohol advertising were emphasized (Anderson *et al.*, 2009). However, evidence is now accumulating to support the value of some (15 of 39 reviewed) generic interventions and some (6 of 11 reviewed) alcohol-specific interventions for reduced drunkenness and binge drinking (Foxcroft & Tsertsvadze, 2011). Effective interventions include the Life Skills Training Program and the Unplugged program. There is also evidence accumulating that programs targeting children with disruptive behavior in elementary school, such as the GBG (Good Behavior Game) also reduce the risk of substance use in adolescence (Castellanos-Ryan *et al.*, 2013).

Universal preventive programs: nicotine

The probability of quitting smoking is inversely proportional to the age of initiation so that delaying the age of smoking initiation is crucial.

In a well conducted meta-analysis, combined social competence and social influence programs showed, on average, a 12% reduction in smoking onset but these effects were only observed a year or more after follow up. There was no evidence that any programs changed smoking behavior (Table 42.1) (Thomas *et al.*, 2013)

An incentive-based program, the Smoke Free Competition, targeting 11–14 year olds, has been implemented widely (16,000 students in three European countries) although incentive programs have not been shown to prevent smoking initiation in youth (Isensee and Hanewinkel, 2012; Johnston *et al.*, 2012). However, approaches using peers show promise. The ASSIST study from the UK (Campbell *et al.*, 2008), used “trained” students aged 12–13 years to spread and sustain new norms of nonsmoking behavior through informal everyday conversations using social networks in schools over a 10 week intervention. Evaluation of 10,000 students 1 year after the intervention showed a 23% reduction in the likelihood of being a regular

smoker and was estimated to be cost effective, even though the effects of the intervention attenuated by 2 years.

Targeted programs

Programs targeting children at high risk of substance abuse that involve both school and home show some promise (Carney and Myers, 2012; Bröning *et al.*, 2012). A recent systematic review of ten targeted prevention programs in school settings reported a mean effect size of 0.2 but effects between programs varied widely (Norberg *et al.*, 2013).

Mentoring programs used particularly in the US to deter alcohol and other drug initiation in high risk youth have yet to show effectiveness (Thomas *et al.*, 2011).

Use of computers

Computerized drug prevention programs in schools have been shown to delay smoking initiation and reduce alcohol and illicit drug use, albeit with small effect sizes (Champion *et al.*, 2013) but this is a rapidly growing field and technology may assist delivery and increase access to interventions in the future.

Depression and anxiety

Given the prevalence and cost of depression and anxiety in children and adolescents, (World Health Organization, 2008) a number of school-based programs have been developed to try and prevent the onset of disorder or to intervene early. Schools may also play an important role in supporting the recognition and treatment of anxiety and depressive disorders. While depressive and anxiety disorders have different presentations and trajectories over time, they are frequently comorbid and prevention and early intervention studies typically measure symptoms of both types of disorders, and, if effective, usually have a significant effect on both disorders.

Generally, school-based depression and anxiety prevention programs, both universal and targeted, are based around cognitive behavioral or, less commonly, interpersonal therapy strategies, typically delivered in groups lasting 8 to 12 sessions. While some targeted approaches have been selective (e.g., for students affected by bereavement), usually students at risk are identified using screening for elevated symptoms of anxiety or depression. Groups are run at school by teachers or trained facilitators from a variety of backgrounds. The interventions are usually manualized and some include booster sessions to enhance long-term effect. More recently the use of computers or mobile phones to deliver interventions has been investigated. Some of the better-known programs include the Penn Prevention Programme, the Coping with Stress Course and the Resourceful Adolescent, all targeting depression (Merry *et al.*, 2011) and FRIENDS; and Cool Little Kids targeting anxiety (Mychailyszyn *et al.*, 2012).

Although the rationale for prevention and early intervention for anxiety and depression using school-based programs is clear, it has been difficult to show that the programs are truly effective and studies have a number of weaknesses, most importantly

Table 42.1 Evidence of effectiveness of school-based interventions.

the lack of attention control groups. It has been difficult to confirm initial positive results in large-scale implementation trials. Many rigorous systematic reviews and meta-analyses of programs focusing on depression have not found a convincing effect and have outlined these concerns (Merry & Spence, 2007; Gladstone & Beardslee, 2009). A more recent meta-analysis was more hopeful about effectiveness (Merry *et al.*, 2011), although there were still a number of weaknesses in the studies. Disappointingly, a subsequent large-scale study in the UK, did not show effect despite rigorous design and the use of a program previously shown to have some efficacy (Stallard *et al.*, 2012).

A recent meta-analysis of cognitive-behavioral school-based interventions focusing on anxiety, particularly those targeted to students at higher risk, were moderately effective for both anxiety and depression, with larger effect sizes for anxiety (Table 42.1) (Mychailyszyn *et al.*, 2012). The quality of the studies included in this analysis was variable.

Over the last decade, a large number of programs targeting internalizing problems in schools have been developed and evaluated but results have been mixed, and attempts to roll-out interventions have not led to clear improved outcomes. The evidence may be more robust for anxiety disorders. Until robustly designed implementation studies show good effect, it would be premature to disseminate these programs widely.

Schools have an important role to play in providing or supporting *treatment* of anxiety and depression in students. The prevalence of the disorders is such that secondary mental health services will not be able to provide treatment for all those affected by these disorders. Furthermore, a large proportion of young people with these disorders are never treated. Screening for depressive disorder and providing treatment in school settings could help address this problem, although evidence supporting this approach is not yet available (Williams *et al.*, 2009).

Posttraumatic stress disorder

Traumatic stress reactions may be displayed in the school setting as increased aggression, anxiety, behavioral problems, developmental regression, psychosomatic complaints and school avoidance. Universal school-based programs have been developed using psycho-education, cognitive-behavioral strategies and a variety of other approaches to address the impact of a variety of disasters. These are delivered by teachers and aim both to increase resilience by preventing PTSD and other symptoms, and by treating PTSD. Examples include the ERASE-STRESS program (Berger & Gelkopf, 2009) and the “Cognitive Behavioral Intervention for Trauma in Schools” (CBITS) (Stein *et al.*, 2003). The evaluation of these programs is complicated by marked heterogeneity in the populations studied, noncomparability of trauma exposure, and the lack of replication studies. Systematic reviews of studies that use primarily CBT techniques have shown small to moderate effects on depression and anxiety symptoms and small beneficial effects on PTSD symptoms in some reviews (Rolfesnes and Idsoe, 2011), but not others (Tol *et al.*, 2011).

Eating disorders

While preventing the onset of eating disorders is appealing and a number of programs have been developed, there is little evidence of efficacy (Pratt & Woolfenden, 2002).

Autistic spectrum disorders (ASD)

There is increasing interest in how the educational environment can support inclusion for the growing numbers of students with ASD in mainstream school (Crosland & Dunlap, 2012). A pragmatic approach has been taken by schools using strategies including; managing challenging behaviors using positive behavioral support techniques; teaching self-management and social skills and anticipating and mitigating the effects of the inevitable changes in routine that occur in schools. It has been postulated that the school setting will provide opportunities for more appropriate socialization by increasing the number of interactions with typically developing peers such as a specialist intervention targeting conversational language skills (Adams *et al.*, 2012) and using trained teachers supporting small peer social skills groups in the classroom (Cappadocia & Weiss, 2011). While these approaches appear sensible, there is no evidence that they are effective.

Computer-based interventions programs have been developed to teach social, emotional and literacy skills to young children with ASD and may be useful for children who are less responsive to traditional teaching approaches (Ramdoss *et al.*, 2012) but whether these therapies facilitate generalizability into real world social interactions is not known (Rao *et al.*, 2008).

Suicide prevention and postvention

Youth suicide is of concern and school-based suicide prevention strategies that include approaches that encourage positive mental health, and improve the detection and management of underlying mental illness, particularly depression, are well accepted as sensible by many mental health professionals even though there is no clear evidence that they are effective. It is logistically difficult to carry out studies to prove effectiveness. There is no evidence that school-based programs that target awareness of suicide directly are effective, and some evidence that they may do harm (Collings & Beautrais, 2005; Beautrais & Mishara, 2007) and on current evidence, these should not be implemented.

Schools will also sometimes have to deal with the aftermath of the suicide of one of their pupils and in doing so should work with local child and adolescent mental health services. Recommended steps in “postvention” usually include strategies to reduce contagion. Because of the known phenomenon of cluster suicides, schools are encouraged not to sensationalize suicide, to restrict the amount of detail about the method of suicide and to avoid either glorifying or condemning the victim of suicide. Identification of vulnerable students known to have risk factors and for whom the suicide may act as a trigger is often advocated. Providing support for the school community and families are important components of the school response. There are some good web-based resources providing

detailed information about postvention responses for example http://www.nasponline.org/resources/intonline/HCHS2_weekley.pdf and <http://www.headspace.org.au>.

School absenteeism

There are a number of different problems that may lead to absenteeism from school. These have been variously defined but include truancy (unexcused, illegal, and surreptitious absences) school refusal (difficulty attending school associated with emotional distress), and school phobia (difficulty attending school because of a specific phobia) (Maynard *et al.*, 2012).

A large number of programs have been developed to reduce truancy with model programs listed on the OJJDP website (U.S. Department of Justice), although the criteria for choosing the model programs on this site are not clear. These programs most commonly include school interventions, with counseling, CBT, mentoring, behavioral interventions, and social work being common components.

School refusal and school phobia are usually treated with CBT and a coordinated approach between the clinician, the family, and the school is necessary for a good outcome (Chapter 38).

A review of the literature on programs for persistently truant students showed modest benefit from targeted interventions on attendance outcomes (Maynard *et al.*, 2012). There were minimal differences in effects across program types and modalities with no one program type or modality standing out as being more effective than any other. There was insufficient evidence to support the current “best-practice” recommendations that collaborative and multimodal interventions are more effective than programs that are not collaborative and single modal interventions.

Evidence for managing the anxiety that underlies school refusal is reviewed in Chapter 60.

School absenteeism is of concern and requires active intervention. For truancy, mentoring and behavioral strategies are likely to be most effective, while school refusal is best managed by addressing the underlying anxiety. In both cases, the involvement of school personnel and families will be key to successful management.

Bullying

Bullying is defined as physical, verbal or psychological abuse or intimidation intended to cause distress or harm to the victim. There is an imbalance in power so that the more powerful oppressor bullies the less powerful victim. Bullying is usually perpetrated over a prolonged period. Cyber bullying, where bullying is perpetrated through mobile phones or the internet with a potentially very large audience, has been of increasing concern particularly given the ease with which an anonymous person can attack (Pearce *et al.*, 2011).

Although bullying in schools has probably always been present there is increasing public attention and concern over recent years. Prevalence rates are around 20–30%, with clear adverse effects on mental health (Jimenez Barbero *et al.*, 2012).

Anti-bullying programs, from kindergartens to high schools, generally comprise developmentally appropriate components of both universal and targeted approaches. These include:

- 1 a global school policy that encourages and supports the value of all individuals;
- 2 classroom-based strategies targeting behaviors, student attitudes and beliefs to improve relationships both between students and between teachers and students; and
- 3 increased supervision in the playground.

The first national anti-bullying programs were developed and implemented in Norway in the 1980s (Olweus, 1996). Although early meta-analyses showed minimal effects, more recent analyses have produced more encouraging findings (Ttofi and Farrington, 2011) (Table 42.1).

There is ongoing debate about the optimal time to intervene (Smith, 2011) and about the effectiveness of various components of the programs, particularly the possible negative effect of peer support schemes such as peer mediation and peer mentoring for bullied students and the type of disciplinary practices used for bullies (Ttofi & Farrington, 2011). The current view is that the most effective approach is implementation of anti-bullying programs across the entire school age range with multi-disciplinary professional support and parental involvement to ensure that the social and cultural milieu of the school is considered.

Currently the KiVa anti-bullying program is being implemented and evaluated nationwide in Finland with impressive initial results (Salmivalli *et al.*, 2011). There is mounting evidence of the public health importance of anti-bullying programs in schools (Knapp *et al.*, 2011). There is a large overlap between cyber-bullying and other bullying (Lindfors *et al.*, 2012) and while evidence on specific approaches to address cyber-bullying is accumulating, appropriate modification of known anti-bullying strategies should be used to tackle this problem (Pearce *et al.*, 2011).

School-based mental health in practice

As discussed earlier implementation of school-based mental health services may take many different forms. It is important first to establish the priorities for the school and for local mental health services. Because of the different focus of schools and mental health services, liaison with school personnel to establish a shared model for intervention is essential. Tensions may arise when mental health professionals believe that services can be delivered effectively in schools, while school personnel are more focused on the delivery of education. Similarly, it is important to ensure that there is clear communication with all the relevant staff, both those managing the schools and those who would deliver the services.

Addressing mental health problems in the school context requires adequate staffing and adequate training. Both should be addressed in any plan to enhance the provision of mental health care in the school setting. Clinicians from child and adolescent

Box 42.1 Tips and traps for practitioners working in schools

Do make sure that you have talked to all the relevant people
 Do establish relationships with key people: visiting schools in the area served by a clinical service
 Do use technology—skype, text etc
 Do be active about communication—check up on progress, have a strategy so the school is in the loop about what is happening in the mental health service
 Do check you have a shared understanding about what happens

Do understand that there is a different culture within the education sector around confidentiality, parental involvement and consent
 Do take into account the school year including the term structure, and the need to work around particularly busy times, like exams and major school activities.
 Do plan ahead. It is often easier to start things at the beginning of a school year, which requires planning well before the end of the previous year.

mental health services may play a key role in providing training. It should be noted that the use of manuals may not appeal to school teachers, who are used to tailoring their teaching to the educational and developmental levels of their students.

Child mental health professionals may support school staff to help children and adolescents with mental health problems in a number of ways. Active liaison with school personnel over individual students with mental health problems is useful. Having a meeting with some of the key teachers involved with the student may allow the clinician to provide essential information about the disorder, what level of function could be expected, the symptoms experienced and the likely course of these, appropriate ways to respond, signs of relapse or need for specific care, side-effects of medications and the ongoing role of the child and adolescent mental health team. Schools may appreciate resources to support them as they implement interventions, but unless these are regularly updated and are appealing and practical they may sit unused on shelves.

In England, the nationwide program, targeting mental health in schools (TaMHS), was started in 2008 and provides a framework to guide schools in the development of services for students at risk of or experiencing mental health problems suitable for their particular community and context. The framework provides practical information to guide. Three studies evaluating the impact have been carried out:

- 1 A large RCT;
- 2 A 3-year longitudinal study; and
- 3 Qualitative interviews with TaMHS workers, school staff, parents and pupils.

Overall, the findings supported the use of this approach although findings were mixed. TaMHS led to reduced behavioral but not emotional problems in younger but not older students. Providing information and good inter-agency working correlated with better outcomes in secondary schools. Overall, the intervention was well received (Wolpert *et al.*, 2013). This is a recent and promising initiative and further refinement is likely to lead to improved outcomes in the future.

Conclusions

In summary, schools provide a good site for the detection and intervention of mental health difficulties in students, although

young people who do not attend school generally have higher mental health needs than those who so.

A wide range of interventions for health promotion and universal and targeted prevention have been developed, with some encouraging results from studies, particularly those targeting behavior. Translating programs shown to be effective in research settings into effective programs in practice has been difficult, while a number of programs that have been implemented in practice do not have data supporting their effectiveness. Further work is needed in most areas to ensure that implementation is optimized and positive effects confirmed.

Developing school-based services requires a strategic approach, with collaboration with school personnel and attention to the wider context of the child or adolescent. Variable resources globally result in variable distribution of school-based mental health services across different nations, and those most in need of services often have very poor access. Global initiatives to address this disparity have been developed and enhancing and extending these will require support from mental health professionals in more advantaged countries.

The appeal of school-based services is undoubted, but given the gaps in evidence it is important that enthusiasm for this approach does not trump evidence and that rigorous implementation trials on promising programs are carried out in the coming years.

CHAPTER 43

Pharmacological, medically-led and related treatments

Eric Taylor

Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Introduction and regulation of psychoactive drugs

Discovery

The initial discovery of psychotropic actions of drugs has usually relied on unplanned clinical observation. Drugs used for other purposes have been found to have beneficial actions on the mind. Historical examples include: the central nervous stimulants—benzedrine having been introduced for postlumbal puncture headache, isoniazid for tuberculosis, and neuroleptics for premedication, especially hypothermia. A current example includes a drug modifying glutamate (riluzole), whose main indication is for amyotrophic lateral sclerosis, but which appears to have potential for treating some forms of depression. It is likely that systematic analysis of large databases will eventually find psychiatric potential in medicines used for other illnesses.

More recently, ideas for new drugs have come to be derived from the understanding of neurochemical targets and the screening of many molecules for their actions on those targets in vitro and in animal studies. The full potential of this method is still to be realized, so serendipitous discovery will keep a place for some years to come. The small number emerging as having therapeutic potential then undergo a planned—and expensive—process of clinical trials. Figure 43.1 illustrates the phases of testing and development

Young people are seldom involved in the early phases, because of the unpredictability of a new drug and the need for safety.

Even at Phase 3, where trials are designed to persuade drug regulators that a market license should be given, children have often been excluded; with the result that pediatric use is inadequately researched and very often not licensed.

Judging clinical trials

Clinicians will therefore need to understand the trial literature as it develops and extends. The quality of a trial needs to be judged in order to understand how much weight can be given to its conclusions. Its power (and therefore number of subjects), clarity and appropriateness of aim, outcome measure and comparator group, randomization, “blindness,” and correct analysis all enter the judgment, as described in Chapter 14. In practice, therefore, prescribers are strongly influenced by systematic reviews, guidelines, and the advice of expert “opinion formers.”

Difficulties emerge when a new drug has a substantial evidence base in its favor, but has not yet gone through the official procedure of approval. In general, caution is advised, especially for the nonspecialist prescriber. Safety concerns sometimes appear only in the later stages of drug development. An experimental treatment should not be preferred to an established one unless the evidence is very clear; its place would be when the full range of standard therapies has failed.

Recommendations, guidelines, and protocols

The process of developing evidence-based practice usually starts with a systematic review of Phase 3 (and other) trials. All the published evidence needs to be collected—and often unpublished as well, to safeguard against bias from nonpublication of negative or inconclusive results. When the evidence allows, estimates of effect size are made, tested for whether there is a consistent story, and pooled for an overall conclusion about efficacy. This is not yet a recommendation, but only a description of the trial evidence; it requires experts on trials and analysis rather than clinicians. The draft then receives a critique from expert clinicians who can incorporate considerations of what is

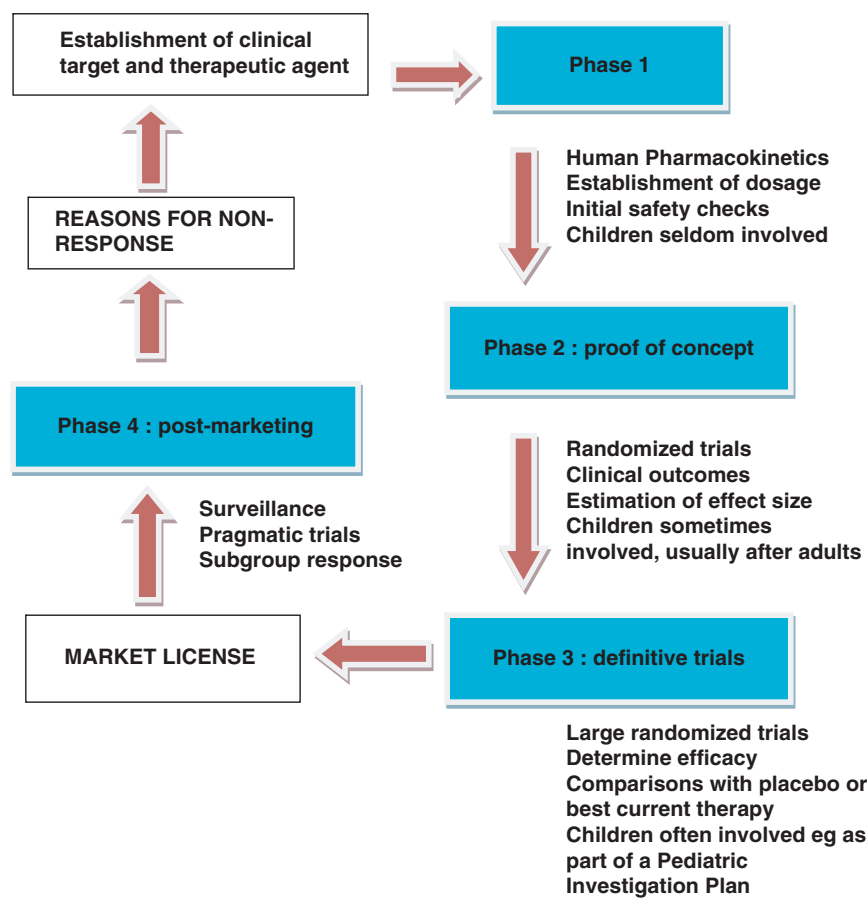

Figure 43.1 Establishing a new medication.

realistic and safe, the impact on quality of life, and the extent to which a new treatment compares favorably with existing practice. For instance, the literature review for attention deficit hyperactivity disorder (ADHD) undertaken by the (English and Welsh) National Institute for Health and Care Excellence (NICE, 2009) would on its own indicate that dexamfetamine (dextroamphetamine) should be the first choice of therapy because of high efficacy and low cost; but expert consensus did not adopt the recommendation because of uncertainty about its safety record and its popularity as a recreational drug.

The resulting recommendation can then be modulated into a guideline—typically, at a national level. The cost of the intervention and its acceptability to the public need to be brought in; they vary from country to country; and economists, users and clinicians from primary and secondary care need to be added to the review. Guidelines by their nature cannot apply to every individual. The prescriber, not the guideline, has the responsibility and must consider the individual circumstances. A particular service may want to draw up a detailed protocol of how treatment should be given—in which case it will need to consider whether it will be applicable to all groups in the community it serves. Guidelines do not have formal legal status. In many jurisdictions, however,

a demonstration that guidelines have been followed has been a successful defense against malpractice litigation.

Licensing, international differences, and off-label use

National and supranational regulators issue a license to a company to market a drug, not usually to individual professionals to prescribe it. (In a few instances, for example for controlled drugs [including stimulants], governments have restricted prescribing to specified centers). Countries vary in their requirements. The classical requirement in the USA has been for two trials, from different centers, showing superiority to placebo; in Europe, for demonstration of superiority to current standard therapy. In many countries there is consideration, not only of efficacy and safety, but of cost. For many drugs, a license has been issued only for adults. They may still be prescribed “off-label” for young people, but the absence of official dosages and safety surveillance can cause confusion. The problem is not only for psychotropic drugs, but occurs across the whole of medicine. In some countries, however, there is officially formulated advice, such as the pediatric version of the National Formulary in the UK (Pediatric Formulary Committee, 2012); or the market license holder will give its recommendations.

International differences and secular trends

There have been large, recent increases of drug prescription of certain drugs in many countries. The number of outpatient visits, by young people in the USA, at which antipsychotics were prescribed rose by some 600% during the decade from 1993 to 2002 (Olfson *et al.*, 2006). In the UK, stimulant drug prescriptions approximately doubled between 2003 and 2008 (McCarthy *et al.*, 2012); and the diagnosis of ADHD increased in tandem (see Chapter 55). Stimulant use in the Netherlands increased some eightfold between 1996 and 2006 (Trip *et al.*, 2009).

Different reasons apply for these increases in different places. In the UK and Netherlands, the increase in stimulants was from a very low base rate (4.8 per 1000 in UK, 2.6 in Netherlands) and followed the reintroduction of methylphenidate to the market and an increased willingness by the medical profession to recognize ADHD as a medical problem. In the USA, increased prescription for adults with ADHD and increased willingness to diagnose bipolar disorder in young children may well have contributed to rising rates. Nevertheless, Rapoport (2013) has argued that the USA now suffers overmedication and an excessive exposure of children to the dangers of antipsychotics (and indeed of other drugs). She attributes this to the economic contingencies applying to medical practice, such as an insistence by managed care that expensive physicians should be used for what they are uniquely qualified to do—prescribing—and so confining their work to medication clinics. Reimbursement policies may also favor the use of drugs over psychological approaches.

There are sometimes cultural reasons for very low drug use, as in France where (for instance) stimulants are used at a rate as low as 1.8 per 1000 (Knellwolf *et al.*, 2008). In many parts of the world, however, medicines are simply unavailable (Taylor, 2013). Medicines may be priced too high to be available (as in China) or there may be too few medical doctors to deliver them (as in most low- and middle-income countries). The World Health Organization advises on which drugs are economically affordable. Paramedical workers can be trained to deliver drugs effectively, provided that protocols are clear and there is access to specialist advice.

Place of medication in therapeutic planning

Targets for medication

Different medicines have different effects. Serotonin reuptake inhibitors (SSRIs) affect anxiety but not ADHD; the opposite is the case for stimulants; some tricyclic antidepressants affect obsessiveness but not depression, while others affect ADHD but not depression.

Treatment planning, therefore, needs the physician to formulate a clear target. It should be clear enough to allow explicit monitoring, practical enough to be susceptible to change, simple enough to allow explanation to the child and family, and acceptable enough to be followed by them. There may of course be multiple targets (for instance, to reduce obsessiveness, lift mood,

and improve social relating)—but it is best to keep clarity about the intended gains and review them separately.

Targets are very often symptomatic rather than diagnostic. They stem from the formulation of the whole case, not simply the diagnosis (see Chapter 32). They are frequently directed, not at the whole diagnosis but at one component of it (e.g., at reducing the hallucinations and delusions in schizophrenia, so that persistence of negative symptoms is not necessarily taken to show that the drug is failing). Furthermore, many child mental health problems act as dimensions that cut across formal diagnoses: stimulants, for instance, may reduce the component of impulsive hyperactivity even if it occurs in the presence of autism, or epilepsy, or conduct disorder. From this perspective, it was an error that DSM-IV did not allow the recognition of ADHD in the presence of autism, and DSM-5 has rightly changed the policy. Similarly, it may be valuable to recognize the presence of depression in a person whose major diagnosis is that of a reaction to trauma and to consider antidepressant treatment.

Targets can also refer to the course of a condition rather than immediate symptom reduction. Reducing the risk of future episodes in a person with recurrent depression is a valid target and can be measured. Each target can be observed as a hypothesis about the nature of the child's condition (see Chapter 32) and each treatment trial is testing a hypothesis.

Ultimately, people are treated, not symptoms. One should not lose sight of the wider picture in pursuit of a targeted symptom reduction. For many people with Tourette's disorder, for instance, the hazards of drugs used in assertive tic reduction will outweigh the benefits of partial suppression; and learning to be more accepting of their tic symptoms and resist the taunts of others can be a better long-term strategy than medication.

Pharmacological versus psychological interventions

Prescribers should know in detail about the benefits and hazards of the available interventions for the chosen target—or be able to find out. Furthermore, they should be able to advise their patients of the best treatment for them, even if they are not in a position personally to provide it. Behavior modification approaches, for example, are in general a safer approach than medication for aggressive behavior and can often be effective (see meta-analysis by NICE, 2013). The practitioner should, therefore, be guiding the family towards the appropriate provision rather than moving straight to medication.

On the other hand, it is often incorrectly thought that medication is a last resort, to be used only after all other methods have failed. The hazards of nonphysical treatments need also to be taken into consideration. In some families, for instance, a prolonged failure to identify improvement may lead to such lack of confidence in the treating service that effective medication is never started. (This can happen, for instance, in blindly following NICE recommendations for a 3-month period of psychotherapy before antidepressant medication). If, as suggested

by the TADS research (March *et al.*, 2004), there is a lower rate of suicidal thinking in depressed young people treated with the combination of fluoxetine and CBT than in cases treated with either monotherapy, then including an antidepressant from the start could prove a safer policy. The judgments about the initial treatment should be based on the individual case, taking into account: The safety and efficacy as known from trials, any predictive factors that apply to the individual, the need for rapid action in urgent cases, the wishes of the child and the family and (other things being equal) the cost of the treatment. The family should be taken firmly into the decision-making process—especially when the balance of evidence is not tilted strongly towards one or the other treatment.

The choice of physical or psychological intervention does not usually depend upon judgments about cause. The physical changes in the brain after trauma (see Chapter 59) do not imply that medication is the best form of intervention for posttraumatic stress disorders. Similarly, the potential of psychological deprivation to give rise to ADHD features (see Chapter 55) does not imply that the treatment of such cases should be only psychological. The rationale for most drugs in current knowledge is based on symptom reduction rather than modification of initiating cause.

Pretreatment assessment

The specification of the target(s) for treatment will lead to a decision about how to measure them and track the impact of intervention. The rating scales used in research trials will be a good starting point and are usually used when the goal is a reduction in complex behavior patterns, such as ADHD. Sometimes, however, it will make better sense for effectiveness to be judged by its impact on a single symptom (such as an isolated phobia), or to include a symptom of particular importance to the child and/or family (e.g., insomnia). An individualized problem rating can then be employed. The overall impact on children's function should also be assessed and an evaluation made of the pretreatment status of any anticipated hazards of medication. A checklist of those hazards should also be set up and used in the monitoring of drug actions along with the selected outcome measures.

Explanation and advice

Families and children come with very different sets of knowledge and attitudes about medication. The internet has made detailed information very much more available to the public—sometimes so contradictory that the result has been more to confuse than to empower. For some, medication is welcome as an affirmation of the medical status of the child's problem and a relief from accusations of poor parenting. Others will have been led to very high expectation of what drugs can achieve. On the other hand, some parents will be strongly opposed to the use of drugs as unnatural and dangerous. Children may understand a "drug" as something that is dangerous, belittling or addictive. Most will bring a mixture of hope and fear. The assessment should include an appreciation of the mix in the individual case and of how the

family's views interact with its community of friends, relatives, neighbors, teachers, and previous professionals.

Cultural and national differences and controversies help to inform the variety of beliefs. Public attitudes in many countries have been strongly influenced by perceptions of whether the treatments are natural or artificial. Some families, for instance, request the provision of St John's Wort (*hypericum*)—a chemical which carries greater hazards (e.g., of immunological and cardiovascular problems) than do the licensed drugs for depression and ADHD, but which brings the (false) reassurance of coming from a plant rather than a laboratory. The (UK) Academy of Medical Sciences (2008) made a public consultation about the use of drugs in people without formal psychiatric diagnoses: approval or disapproval was closely connected with whether the substance was natural and acceptable (e.g., caffeine) or synthetic (e.g., "Prozac"). Some spiritual leaders discourage their disciples from accepting drugs rather than relying on their faith.

Another strand in the debate in some countries has come from distrust of commercial practices. In many cultures, deference to physicians is being replaced by a view that medical psychiatrists have come to be untrustworthy and even venal. Medical opinion leaders have often been seen to accept money from pharmaceutical companies, which can be viewed as disqualifying their advice. Prescribers are advised to refrain from accepting gifts or other benefits that they would be unhappy to be known to their patients or revealed in the media.

A key task for the prescriber is therefore to understand, and responsively discuss, the understanding that children and their families bring to a recommendation for medication. Children will have a changing understanding as they develop and will need the opportunity to discuss their treatment in different ways as they grow older. Singh (2012) applied methods of qualitative interviewing for children and her findings emphasized that they frequently attain a sophistication of understanding, identifying positive and negative aspects of the treatment. Autonomy and authenticity become important ways in which adolescents come to think about themselves. Responsive discussion is needed and it is an influence on how the child and family make large decisions about whether to take the treatment at all, and smaller ones about dosing regimes. Families need to be willing partners in issues such as the generation of the clinical hypotheses and the need to test them with a trial that is long enough—depending on the drug—to test the hypothesis that the drug is effective.

Consent

Consent to medication means the uncoerced and informed agreement to treatment by a person who is competent to give it. Children may not be competent to make the decision, and their parents or guardians do it on their behalf; but their assent should be sought and their views respected even if they are over-ruled. The amount of information that needs to be given should be tailored to the person. The detailed information in the product package is legally specified and often useless to the reader by virtue of its length and lack of prioritization. The

Box 43.1 Information necessary for consent.

The condition to be treated
 Nature of proposed treatment
 Nature and probability of material risks
 Benefits to be expected

Physician's inability to predict results
 Irreversibility (if applicable)
 Likely results of no treatment
 Likely results/risks/benefits of alternatives

prescriber becomes the key source of information. He or she has the professional duty to brief with enough information to enable a rational choice, if the patient is fit to receive the information and wishes to receive it. One legal formulation of the information that should be given derives from the case of *Hamish v Children's Medical Center* 1982 and is summarized in Box 43.1.

Compliance

A necessary step for a drug to be fully effective is that it should be swallowed. A lack of adherence to the prescriber's intentions is very common and the reasons for it need to be understood. There are many people in a child's network who can exercise an effective veto over medication, and some of them will not have had the benefit of full explanation. Estranged parents, grandparents, teachers who are new to the child, and professionals from disciplines hostile to medication are the commonest obstacles to the therapy. The remedy will probably be to explain the rationale to them. Sometimes, they will be able to observe the difference between medication and the lack of it with their own eyes (as with a temporary discontinuation of stimulants); but for many types of drugs (e.g., antidepressants) a premature discontinuation can have adverse effects. The responsible parent will then need to draw on the trust that has been built up with the prescriber and her (or his) own resolve.

Moreover, children's own attitudes play a strong part in adherence to expected regimes. There are several influences that can lead to their not taking the treatment, and they call for different types of action. Simple forgetfulness is common, especially when child or parent is afflicted with problems of memory or attention. Dispensing in calendar packs can help, as can charts in which medication is included with other daily chores. Taking tablets can be treated as a learned behavior and encouraged with star charts and the like. Simplicity of administration also helps—longer-acting drugs can be taken once a day and can therefore be more clearly under parental control. Children can often encounter considerable stigma if they are known to take psychotropic medication, especially from other children but sometimes from teachers. Extended-release preparations or long-acting drugs can then allow a single daily dose in the morning or evening and children often value the privacy and confidentiality that this brings.

Many children, especially those with autism spectrum disorders or intellectual disability, have an inability or a marked reluctance to swallow. Liquid preparations are often available; when they are not (e.g., for most controlled drugs) then

granular preparations can often be swallowed much more readily, for instance by being sprinkled on food. (Surreptitious administration is not advocated, however, partly because of the breakdown of trust that can follow when the child discovers the truth). The taste of drugs can also be aversive; and some antidepressants (fluoxetine, escitalopram and bupropion) are particularly likely to cause a dysgeusia and need to be replaced with another antidepressant. Tart juices (such as lemonade), cold or iced drinks and food, and sugar-free chewing gum can all help to get rid of unpleasant taste sensations.

Adverse effects are also a reason for noncompliance and some of them may not be obvious because they are not volunteered or included in checklists of adverse effects. Sexual problems, for instance in ejaculation, are quite common with SSRIs and can be distressing to adolescents. A feeling that one has lost one's funny side can be expressed by children treated for ADHD: it is not always veridical, because it may be that children have stopped laughing *at* one rather than *with* one; but it may be a pointer to a lack of spontaneity and an overly high dosage. Some young people, who have rightly been warned against the dangerous effects of cannabis, may have understood or been told that it must never be combined with prescribed medicine and prefer to omit the medicine than forgo the cannabis. There is in fact no major interaction between stimulants and cannabis, and it is often better to permit the combination than to lose the benefit of the medicine. Other illegal drugs (see Chapter 66) are rightly regarded as contraindications outside very specialist settings.

In adolescents, development issues of autonomy become very important. If during childhood medication has been imposed coercively then a hostile reaction to it is only to be expected. In these circumstances, it is often possible to return responsibility to the teenager, to allow discontinuation, and to suggest the experiment of finding out how the absence of medicine affects one's progress—as seen by others (e.g., teachers and friends) as well as by subjective experience and family reaction. The goals of therapy may then be renegotiated to be more meaningful to the young person and most of those who need long-term treatment will indeed decide to return to it. The most ominous of the attitude changes is probably emotional: the nihilistic belief that nothing can be done to help one's predicament. This should be taken seriously and addressed vigorously with cognitive (or antidepressive) approaches.

A self-report scale has been developed by Ferrin *et al.* (2012) for young people to describe both positive and negative attitudes to drug therapy, and it may be helpful to track individuals' progress in this way. It is important to maintain positive

attitudes. Good compliance was in one study associated with good outcome over a 5-year period (Charach *et al.*, 2004). This may not be wholly cause and effect. In a meta-analysis across a wide range of adult medical specialties, Simpson *et al.* (2006) found good compliance to be associated with good outcome—even when the treatment was a placebo. The healthy comply well. “Compliance” may be an oversimple goal, if it is taken to mean only accurate obedience to the wishes of doctors and parents. In the long run, perhaps, the model should be that of the intelligent consumer who has learned when and how to take medication in his or her best interest.

All the aforementioned obstacles to compliance can lead to multiple agents being tried but stopped prematurely, before they have had a chance to be effective. It may be necessary to return to such agents later; for instance to a reduced dosage of a drug that was discontinued because of an adverse effect that might well have subsided with time.

Involvement of multidisciplinary team: knowledge and attitudes, communication

Where prescribers have the advantage of working in a multidisciplinary team, care can readily be made comprehensive. Nurses, psychologists, and pharmacists can take on prescribing and monitoring. The initial decision to prescribe can be made after an assessment including several perspectives. The impact of physical treatment on ongoing psychological work can be explicitly considered. In neurodevelopmental disorders, it may be possible to apply therapies such as speech and language therapy for the first time when behavioral disturbance has been controlled medically. It may be possible for the management of anxiety to proceed when initial panics have restricted the opportunities for graded exposure. Conversely, therapists encouraging the exposure to anxiety-provoking situations may be able to request that anxiety-reducing drugs should be withheld.

Two possible problems need to be overcome. First, there needs to be an atmosphere of mutual respect for differing therapeutic approaches so that families are not confused. Second, there should be continuity for the children in their key worker, so that they can have extended conversations over time about their condition and its therapy.

Prescribing: evidence and practice

Developmental changes in pharmacokinetics

The body changes with age in the ways that it absorbs, distributes, and metabolizes drugs. The experience of adult psychiatry cannot be applied without careful revision. Adult doses cannot simply be scaled down on the basis of body weight.

Developmental differences are present at many stages of a drug's journey from mouth to brain. Ionized drugs (many are weak acids) may be less well absorbed from a child's less acid stomach. The great activity of the young liver may oxidize and conjugate drugs more swiftly than that of the adult. Distribution—which is often in the extracellular fluid—may

result in greater dilution for children, in whom there is a greater ratio of water to fat than applies after puberty. For most, the resultant is less bioavailability in children and therefore a need for a higher dose in mg/kg terms. On the other hand, the greater permeability of the blood–brain barrier in children may mean a greater than predicted effect. The complexity forbids accurate calculation and correspondingly Tables 43.1–43.3 show, for the most part, approximate dose ranges rather than mg/kg specifications. Titration according to the individual's clinical response is therefore required. “Start low and go slow” is not only the conventional wisdom, but good advice.

Prescribing errors and avoiding errors

Errors in prescribing and dispensing are responsible for many of the adverse effects reported. Prescribers are advised to have a restricted group of drugs that they know well (e.g., one from each major class) and to be particularly cautious when they go outside that range. They should have a prescribing manual at their side so that they do not have to rely on memory concerning doses at different ages and can check on interactions with other drugs or foodstuffs (e.g., Taylor *et al.*, 2012). They should keep a reference on specific problems about which to warn families in advance (e.g., suicidality with selective serotonin reuptake inhibitors and atomoxetine; and overeating in antipsychotic use). Monitoring should be carefully matched to the expectations of guidelines and protocols.

Stimulants and other antihyperkinetic agents

Methylphenidate, amphetamines, and atomoxetine comprise the approved range of therapies for ADHD (Attention Deficit/Hyperactivity Disorder), in most countries. There is a sound evidence base for them, based on good quality trials and systematic reviews: Seixas *et al.* (2012) review national guidelines: there is a consensus that the licensed drugs all have large effects in reducing the features of ADHD. They are also used in the treatment of narcolepsy and in counteracting the obtunding effects of anticonvulsant drugs. Table 43.1 indicates their dosage ranges, duration of action, and legal status and Chapter 55 describes their application to the clinical problems of inattention, impulsivity, and inattention. The controlled status of the stimulants reflects their capacity for inducing euphoria and craving if they are taken by a rapidly acting route (such as intravenous injection or inhalation). Taken orally, however, and in therapeutic doses, there is little such risk, and its management is described in Chapter 55.

The pharmacology of efficacious drugs is rather diverse, but all have effects on catecholamine receptors (Heal *et al.*, 2012). Methylphenidate and the amphetamines inhibit the dopamine transporter; this and other actions create large increases in dopamine and norepinephrine in the prefrontal cortex and dopamine in the striatum. Atomoxetine inhibits the norepinephrine transporter; the functional effects include enhancing the brain levels not only of norepinephrine itself, but also of dopamine in many parts of the brain except the

Table 43.1 Considerations specific to individual antihyperkinetic drugs.

Drug	Preparations	Dose (per day)	Duration	Legal status
Methylphenidate	Immediate-release	5–60 mg in divided doses	2–4 hours	Licensed for children in many countries; controlled as a misusable drug
Extended release Methylphenidate (proprietary names given)	OROS (osmotic release) Concerta Equasym-XL (beaded) Medikinet-retard (beaded)	18–72 mg single dose 10–60 mg single dose 10–60 mg single dose	Up to 12 hours up to 8 hours up to 8 hours	Controlled drugs
Dexamfetamine	Immediate-release	2.5–40 mg	3–6 hours	Licensed in many countries for children. Controlled drug
	Lisdexamfetamine	20–70 mg	10–13 hours	Licensed in many countries. Controlled drug
Atomoxetine		0.5 mg/kg for first week, then 1.2 mg/kg; max. 1.8 mg/kg	Prolonged	Licensed in many countries for children and adults (in Europe, only if treatment started before 18). Not controlled
Alternative antihyperkinetics				
Bupropion		50–200 mg divided doses (or single dose of XL formulation)	c. 6 hours	Not licensed, even for depression, in UK Not controlled Caution re seizures
Clonidine		0.05–0.4 mg divided doses (or single dose of XL formulation)	c. 4 hours	Not licensed for children in most countries Not controlled
Guanfacine (extended-release formulation)		1–4 mg single dose	Prolonged	Licensed in USA, not Europe. Not controlled
Modafinil		200–425 mg single dose	Prolonged	Not licensed for children, due to concerns re skin problems Not controlled

Doses for children aged 6 years or more. They should be regarded as indicative only; individual titration against response is required and some children may need higher doses after appropriate review. Financial costs are not included as they vary greatly between countries. “Alternative antihyperkinetics” includes only those with evidence from randomized controlled trials. The table does not include drugs considered too hazardous for this purpose (e.g., pemoline and desipramine). Dexamfetamine is also known as dextroamphetamine.

striatum. Of the alternative antihyperkinetic agents that lack European approval, bupropion has several actions (including nicotinic) but its value as an antihyperkinetic is probably related to the inhibition of norepinephrine reuptake. Guanfacine and clonidine are preferential α_{2A} -adrenoceptor agonists, and clonidine is used in the treatment of hypertension and migraine. Their presynaptic action may reduce norepinephrine effects and create sedation and depression as hazards of therapy. Modafinil's pharmacological actions are multiple and somewhat obscure but include increase of striatal dopamine as well as effects on norepinephrine, glutamate and hypocretin in the brain; it is used for the treatment of narcolepsy and daytime sleepiness.

Table 43.1 summarizes the dose ranges for children and how long an individual dose can be expected to last. The stimulants are notable for their rapid onset and offset and some extended-release preparations have therefore been formulated and are referred to by their proprietary rather than generic names. Adverse effects (including those on the cardiovascular system) and their management in children with ADHD are described in Chapter 55.

Antipsychotics

Antipsychotics have a clear place in the treatment of schizophrenia and bipolar disorder and a more controversial one, in low dose, for a variety of conditions where the control of agitation, anxiety, and aggression is desired. The evidence about their use is extensive for adults, but very scanty for children and adolescents (except for efficacy in severe irritability in autism and/or intellectual disability, where several good-quality trials have received systematic reviews and, recently, approval by regulators). Knowledge about pharmacokinetics and safety is based mostly on analogy with adult effects. All the antipsychotics have pharmacological actions in blocking dopamine receptors and most also act on the serotonin (5HT) receptors. They differ in the details of which dopamine receptors, and which others, receive the blockade.

The first generation of antipsychotics (FGA: chlorpromazine being the standard) coincided with, and facilitated, the social psychiatric effects of normalizing the lives of those with chronic psychoses. They also had a range of unpleasant adverse effects—including those on the extrapyramidal motor system which may have been even more frequent, stigmatizing, and

Table 43.2 Considerations specific to individual second-generation antipsychotics (SGA).

Drug	Receptor actions additional to generic	Other approved indications	Safety considerations
Risperidone, Paliperidone and others	Generic; see text	Irritability in autism	Risperidone has lower risk for seizures than many antipsychotics
Quetiapine	H1 blocker Alpha-1 adrenoreceptor blockade Low D2 binding	Adjunct in major depression	Sedative Hypothyroidism Low rate of EPS Low rate of epilepsy Low rate of hyperprolactinaemia
Amisulpride Low dose	Inhibit Dopamine autoreceptors	Not approved in USA (possibly helpful for negative symptoms)	Agitation
High dose (>400 mg)	Inhibit postsynaptic receptors Antagonises 5HT-7 Little 5HT-1A, 2A, C blockade	(Possibly helpful for depression)	Q-T interval prolonged
Aripiprazole	Partial dopamine agonist	Adjunctive in major depression Irritability in autism	Less metabolic and endocrine risks than most antipsychotics; somewhat more EPS
Olanzapine	Multiple receptor antagonism including muscarinic M3	Alternative to clozapine in refractory psychosis	High efficacy High rates of obesity, metabolic and endocrine problems
Clozapine	Low D2 binding, high D4 Cholinergic and histaminergic antagonism	Refractory psychosis (nonresponse to 2 SGAs)	High efficacy, low EPS High rates of obesity, metabolic and endocrine problems Agranulocytosis, requiring blood counts Seizures, constipation

EPS = extrapyramidal symptoms.

Table 43.3 Antidepressants.

Drug	Metabolites	Dose (mg/day) ^a	Special consideration
Fluoxetine	Norfluoxetine (active, long half-life)	20–40	The standard for treating depression Interacts with many other drugs
Fluvoxamine	Inactive	100–200	Short-acting, and less protein-bound than others so less likely to cause interaction with other protein-bound drugs
Paroxetine	Inactive	20–40	Short-acting and sedative Anticholinergic side effects
Citalopram, Escitalopram	Desmethylocitalopram (possibly active, long half-life)	20–40 10–20	Most selective Few interactions with drugs that are metabolized by P450 Prolongation of Q-T interval
Sertraline	Desmethylsertraline (much less active, long half-life)	50–200	Should be taken with food which increases plasma levels Inhibits dopamine reuptake

^aCommon maintenance dose range. Doses vary: initial dose is usually half the lower dose given above. These figures are only a guide and individual titration should be undertaken. Children younger than 12 may need lower doses and those younger than 6 require detailed specialist consideration.

disabling for young patients. It therefore appeared to be a great advance when a second generation of antipsychotics (SGAs) appeared, with much less propensity to alter motor control. They became the standard for treating first episodes, especially in young people, with risperidone being the most widely used.

There are, however, another set of metabolic adverse effects that are even more prominent than in FGAs: obesity, increases in blood levels of triglycerides, nonhigh-density lipoproteins, cholesterol and glucose (which may amount to Type II diabetes), and endocrine changes such as hyperprolactinemia

(which can result in inappropriate lactation for both sexes, and polycystic ovaries and menstrual irregularities in females). Constipation can become a serious problem in developmentally disabled children.

The implications for clinical practice are set out in Chapter 57 for schizophrenia and other psychoses, Chapter 56 for motor tics and Chapter 62 for bipolar disorder.

Most of the SGAs share most of the same good and bad effects. They differ somewhat in the profile of receptors affected, and consequently the clinical actions, requirements for monitoring, and safety profile. Table 43.2 sets out the considerations that are specific to some individual SGAs. Risperidone is taken as the standard and the choice among the other antipsychotics is largely determined by the adverse effects in the individual case. For example, aripiprazole may be preferred in the presence or threat of obesity; quetiapine in hyperprolactinemia, quetiapine or olanzapine plus fluoxetine in depression; clozapine (in spite of adverse effects) in nonresponse to other drugs. The blood levels are determined not only by dose level but also by metabolism in the liver. Different SGAs are broken down by different cytochrome isoenzymes. Interactions with other drugs and food substances which inhibit those enzymes (e.g., some antidepressants) or potentiate their action (e.g., some anticonvulsants) will therefore vary from drug to drug.

Antidepressants

Tricyclics

Tricyclic antidepressants act on several neurotransmitter receptor sites, notably serotonergic and norepinephrinergic. They are effective in reducing ADHD features, but not often used because of toxicity (requiring, *inter alia*, monitoring of ECG). They are also effective in reducing symptoms of obsessive-compulsive disorder, especially if they have strong serotonergic activity (e.g., clomipramine), and they can suppress bedwetting. Curiously, however, they have proved ineffective in treating depression in children (systematic review by Hazell *et al.*, 1995).

Selective serotonin reuptake inhibitors (SSRIs)

Selective SSRIs have small to moderate effect sizes as antidepressants and moderate to good effects in the therapy of obsessions and compulsions and anxiety disorder (see Chapters 60, 61 & 63). Distressing adverse reactions include gastrointestinal symptoms and headaches. They can alter the metabolism of other drugs, notably antipsychotics.

Some differences between the various SSRIs are set out in Table 43.3. The main consideration in practice is that of the risk for “suicidality”—usually, thoughts about self-destruction or the valuelessness of life, and occasionally even self-harming gestures or acts (Hammad *et al.*, 2006). Systematic guidance has been developed by national drug regulators and favors fluoxetine (Chapter 63 and Committee on Safety of Medicines, 2003). In practice fluoxetine is nearly always the first choice and others are reserved for situations where fluoxetine has failed,

or is itself contraindicated (e.g., by intolerance), or is likely to cause hazardous interactions with other drugs.

In conditions other than depression, there is a wider choice of antidepressants. While they all increase serotonergic activity, they interact with many other receptors as well. Citalopram and escitalopram are the most selective for serotonin reuptake, fluoxetine the least. By the same token, fluoxetine is most likely to inhibit the cytochrome P450 family of enzymes that metabolize many drugs in the liver; citalopram and escitalopram the least—and therefore the most suitable to administer in combination with other psychotropics. Fluvoxamine and sertraline are less protein-bound than other SSRIs, and correspondingly less likely to interact with other protein-bound drugs (including some anticonvulsants).

Weight gain and metabolic changes are possible adverse effects, but are least prominent with fluoxetine and sertraline in the adult studies from which most of our information is derived (Hiemke & Härtter, 2000). Citalopram and escitalopram appear particularly likely to give rise to sexual dysfunction (a problem which adolescents often resent and seldom express spontaneously). Sertraline appears least likely to cause insomnia.

All the SSRIs can give rise to discontinuation problems, even the long-acting fluoxetine, and patients and families should be warned to avoid stopping suddenly. Interestingly, the effects are not interchangeable. A person who has not responded to fluoxetine may well respond to any of the other SSRIs, and it is not usually necessary to proceed to a drug with a different pharmacological profile such as venlafaxine (Brent *et al.*, 2008).

Newer antidepressants

A wide range is available: norepinephrine-SSRIs (SNRIs—such as venlafaxine), norepinephrinergic and specific serotonergic antidepressants (NaSSAs—such as mianserin and mirtazapine), selective norepinephrine reuptake inhibitors (such as reboxetine), and norepinephrine-dopamine reuptake inhibitors (such as bupropion). None of them are approved for use in children, but some—especially bupropion and venlafaxine—are in wide use for depression or refractory ADHD. Prescribers should regard them as experimental and monitor with particular care for significant complications such as suicidal thoughts and actions (venlafaxine) and seizures (bupropion).

Monoamine oxidase inhibitors (MAOIs)

Monoamine oxidase inhibitors (MAOIs) were the first antidepressants to be developed and are now little used because of their capacity for dangerous interactions with other drugs and some foods (especially those containing tyramine). If, for instance, they are used after fluoxetine then the latter drug must be withdrawn for at least 5 weeks before the MAOI is given. More selective MAOIs such as selegiline, and reversible ones such as moclobemide, have much less risk and have been used with some success in children for treating ADHD (Trott *et al.*, 1992; Rubinstein *et al.*, 2006).

Drugs used for stabilizing mood

Lithium is a mineral, usually administered as the carbonate or citrate salt, with well-established indications in adults for bipolar mania, prophylaxis of depression and mania, and potentiation of antidepressant drugs. It interferes with ionic transport by neurones and may have a variety of effects on neurone chemistry—including effects on the neurotransmitter glutamate, serotonin release, and nitric oxide (Jope, 1999). Its use in children is complicated by uncertainties about efficacy, the need for close monitoring of blood levels and thyroid and kidney function, and the high rate of adverse events in young children (Hagino *et al.*, 1995). Chapter 62 reviews its antimanic uses.

Anticonvulsants and antipsychotics are also used as mood stabilizers. McClellan *et al.* (2007) review and provide practice parameters for their use in bipolar-I illness affecting children. Divalproex, other valproate preparations, carbamazepine, and perhaps lamotrigine are the best evaluated of the anticonvulsants for this purpose. They do not have a sound evidence base for children and their adverse effects—while less troublesome than those of the second-generation antipsychotics described earlier—are not inconsiderable (see Chapter 62).

Other drugs

Benzodiazepines (and other GABA-A promoters such as zolpidem) are widely used in children, but with little scientific evidence for their value or safety. In the treatment of anxiety, they should be very much subordinate, first to psychological treatment and then to SSRIs (systematic review by Reinblatt & Riddle, 2007). The hazards of chronic use include disinhibition, aggression, cognitive blunting, withdrawal reactions, and dependence.

Single doses (or very short-term use) can nevertheless be useful—for instance, in premedication for dental surgery. Short-acting benzodiazepines (e.g., lorazepam) are advised. They can also be helpful in emergency situations involving great anxiety and/or aggression and may be preferred to antipsychotics (such as olanzapine) when there is the possibility that illegal drugs, other hallucinogens or alcohol have contributed to the crisis. There may also be a rapid effect on catatonic states.

Pregabalin is an anticonvulsant drug that binds to a subunit of the voltage-dependent calcium channel and thereby reduces norepinephrine and glutamate activity. It is an effective anxiolytic and is licensed for this purpose, in adults but not children, and in Europe but not in USA. It can be considered for severe cases in young people where SSRIs have failed and is probably to be preferred to benzodiazepines for this purpose.

Hypnotics: Sedative antihistamines, tricyclics, and melatonin all have their advocates (see Chapter 70). Melatonin is a naturally occurring hormone playing a role in the regulation of the sleep-wake cycle and can help children to fall asleep more quickly (rather than extending time spent asleep) (Gringras *et al.*, 2012). Drugs acting as agonists on the melatonin receptor are being developed as treatments for depression and agomelatine has a license, in Europe and for adults, as an adjunctive treatment in atypical depression.

Oxytocin is attracting investigational interest as a promoter of prosocial behavior and empathy.

Drugs affecting endorphin systems (e.g., naltrexone) may also prove to have a role in promoting social behaviors and in moderating pain responses and repetitive self-injury. They are, for the moment, to be observed as experimental.

Dietary interventions

Elimination diets

Substances in the diet can upset behavior either by a toxic effect or by an idiosyncratic effect on predisposed individuals. There has long been concern that food additives can worsen children's behavior and learning and that hyperactivity and irritability in particular can be treated by removing certain colorings (especially tartrazine) and preservatives (especially sodium benzoate) from a child's intake. The possibility came to be regarded as somewhat eccentric and research trials were for the most part inconclusive. In recent years, however, better evidence has emerged. In careful studies such as that by McCann *et al.* (2007), children's behavior was worsened, in the short term in population samples, by mixtures of artificial colorings and preservatives, using randomized double-blind comparison with placebo. The effect was not particularly on children with features of ADHD, nor on children with other evidence of allergy. There was some evidence that histamine degradation gene polymorphisms mediated the effect. The main impact of the research has been on public health rather than clinical psychiatry (Stevenson *et al.*, 2010). In December 2009, the UK government requested food manufacturers to exclude tartrazine from their products, and the issue is under review by the FDA. For the clinician, the key question is whether individual children can be helped if the additives are eliminated from what they eat.

Nigg *et al.* (2012) provided a systematic review and meta-analysis, with the probable conclusion that elimination has a significantly positive effect but that the size of the effect is small. The clearest evidence came from the best quality trials that focused on colorings and used parent ratings. Teachers and observers did not find significant effects, but psychometric tests did find an effect in improving attention. Meta-analysis by Sonuga-Barke *et al.* (2013) had similar conclusions and added that a small effect could still be found by observers not involved in the delivery of the treatment. Small effect sizes in group studies could come from a large effect on a small number of children, or a small effect on many, and the question of how to identify those who will respond is unsolved. Where parents wish to explore the effect of eliminating artificial colors, there is reason for the clinician to support them. (Many families will already have tried before they get as far as a mental health service). Possible adverse effects include an undue restriction of a child's social activities to avoid exposure to additives. Advice should include warning against such restriction, bearing in mind that there is as yet only weak evidence for a helpful effect outside the home.

Elimination of individually identified food substances

A wider range of foods with potentially harmful effects on intolerant individuals has also been proposed. The key evidence comes from studies in which a food has been identified by an open individual trial, and then presented in disguised form, and contrasted with an indistinguishable food known not to provoke an adverse reaction. Randomized controlled trials have received meta-analysis from Sonuga-Barke *et al.* (2013), with the conclusion that there is a statistically significant benefit from the procedure on ratings of behavior—but that the effect is confined to ratings made by parents involved in the administration of the diet.

There are many incriminated foods. The list includes natural foods (e.g., cow's milk, wheat flour, citrus fruit, other fruits, eggs, etc) as well as artificial colorings and preservatives. As a result, the treatment is arduous to deliver and if applied strenuously can result in a seriously distorted diet. One practical approach is with a food diary, linking daily behavior ratings to foods taken and eliminating only those foods linked to deterioration. A full approach, capable of detecting delayed effects, is a period on a very restricted diet (typically, six ingredients only) followed (if problems have disappeared) by a process of introducing new foods, one at a time, to detect the ones that are harmful in the individual case. Such a few-food diet is only appropriate if used as an investigation and for a limited period; it is not recommended as a long-term substitute for normal eating. The advice of a pediatric dietitian, if available, would be very helpful in this rather drastic intervention.

Dietary supplements

Supplementation with long-chain polyunsaturated fatty acids (PUFAs) has the rationale of animal studies, especially on arachidonic acid (AA), eicosapentaenoic acid (EPA), and docosahexaenoic (DHA). Humans lack the enzyme needed to produce these fatty acids and therefore they have to come from the diet. Experimentally induced dietary deficiencies lead to animals showing brain abnormalities, for instance, in functions associated with neural activity such as membrane fluidity, neurotransmission, ion channels, enzyme regulation, gene expression, myelination, and the transport of serotonin. There has therefore been research interest in applications to psychiatry, and trials are accumulating (Freeman *et al.*, 2006). Omega-3 PUFAs (DHA and EPA) appear to have some efficacy in the adjunctive treatment of major depressive disorder (Jazayeri *et al.*, 2008). A systematic review and meta-analysis of trials has indicated a small but statistically significant effect in children with ADHD (Bloch & Qawasmi, 2011). Adverse effects are few, but PUFAs are contraindicated in the presence of bleeding diatheses. Their place in practice is not yet secure.

Families can be advised that PUFAs do not yet command the evidence that can lead to a firm recommendation, and that they should not be preferred to effective medicines; but that the chief disadvantage is only their cost, which is not covered by health insurance or the NHS in the UK. A service may well offer to

monitor response, if only to ensure that established therapies are not neglected. Other food supplements—with vitamins and mineral micronutrients—do not have a sound evidence base and are not recommended for routine use (NICE, 2009); but nevertheless are widely used.

Neurotherapies

Electroconvulsive therapy retains a place in adult psychiatry, but is used very little in childhood and adolescence. Nevertheless, it has a role in treating otherwise refractory cases of severe depression, persistent mania and catatonia. Bertagnoli *et al.* (1990) provide a review of reported cases and Shoirah and Hamoda (2011) provide update. The offensive reputation of the treatment in the public mind would make wide consultation and explanation essential. It is usually regarded as an “irreversible” treatment from the perspectives of ethical review and requirements for informed consent. Expert administration would be necessary.

Nonconvulsive electrotherapies include transcranial magnetic stimulation (TMS) and DC current stimulation (TDCS). TMS involves the use of a magnetic coil on the scalp to produce focal currents in the underlying brain and thereby to modify neuronal excitability. It is used as a diagnostic tool in some neurological disorders. It is capable of showing developmental changes in childhood and detecting immaturity. Compared to adults, children have higher thresholds for activating motor cortex, and a previous pulse produces less inhibition of a succeeding one (Garvey & Volker, 2008). It therefore has promise as a diagnostic and monitoring tool for motor disorders and possibly for the inhibitory dysfunction that is observed in ADHD. Repetitive TMS produces enduring changes, is used experimentally to treat depression in adults, and might become a therapeutic tool. Indications and safety are not yet worked out and it should only be used experimentally and in expert centers.

In TDCS, weak currents (app. 1 mA) are applied to the brain via scalp electrodes. The idea is to manipulate nerve cell resting membrane potentials and make them more or less ready to fire. Activation is accompanied by changes in GABA and glutamate and in neuropsychological test performance. At present, they are tools for research only (Utz *et al.*, 2010), but they are of interest for therapies involving improvements of executive function.

Neurofeedback involves the detection of specific brain signals—usually from the EEG—and rapidly informing the child with a light, sound, or change in a video game when the desired signal is present. It has been a controversial intervention for years, with conflicting results from trials, inadequate methodology and excessive unsupported claims for its value. Recently, however, improvements in study design have made for a better and more positive evidence base in the therapy of epilepsy, dyslexia, and especially ADHD. A recent study on ADHD and providing meta-analyses concluded that “While the [unblinded data] on neurofeedback ... was promising, evidence of efficacy from blinded assessments is required before they can be recommended as ADHD treatments.” (Sonuga-Barke *et al.*, 2013).

Combinations of treatment

There is an increasing trend, at least in the USA, for multiple psychotropic agents to be prescribed to children, sometimes in doses higher than the recommended maxima. This practice is not supported by an evidence base. Polypharmacy has sometimes been held to be wrong in principle. This is too sweeping: one drug with multiple pharmacological actions is not necessarily an advantage over two simpler drugs. It is easier to vary pharmacological actions independently when each action is achieved by a separate drug. In theory, it does not make much sense to combine two pharmacologically similar drugs (e.g., two SSRIs); but our knowledge of pharmacology is not yet precise enough to provide accurate prediction and the wise prescriber goes by empirical evidence about what works. When drugs work in dissimilar ways, there is a clearer rationale for combination. The major consideration in combining drugs becomes the presence of interactions between them and these can be quite complex. Two simple steps are important for the prescriber: the first is to become very familiar with one drug of each main class, know it well (including its interactions), and use it preferentially and the second is to use a manual or a website that lists interactions (e.g., Taylor *et al.*, 2012; Pediatric Formulary Committee, 2012; epocrates.com).

Research and future developments

The next few years are likely to witness emerging trials that will fill some of the evidence gaps noted throughout this chapter. The appearance of new drugs, however, may slow down. Pharmaceutical companies have come to view psychiatric conditions as unpromising, because of their complexity, their heterogeneity without clear segregation of subtypes, the uncertainties about how to stage disorders, the scarcity of good preclinical models, the costly experience of drugs failing to meet modern standards of efficacy and safety, and the reputational damage that companies suffer from past mistakes and antidrug attitudes. Better ways of using existing drugs may result from better monitoring (e.g., from brain imaging) and improved prediction (e.g., from pharmacogenomics). Development of cognitive-enhancing drugs will lead to racetams, nicotine analogues, and many others—to join the existing enhancers such as stimulants, D-cycloserine, and modafinil. Tensions will emerge on drug use outside diagnostic boundaries. Psychiatrists will have much to learn.

C: Contexts of the clinical encounter and specific clinical situations

CHAPTER 44

Refugee, asylum-seeking and internally displaced children and adolescents

Mina Fazel, Ruth Reed and Alan Stein

Department of Psychiatry, University of Oxford, UK

Introduction

Children forced to flee from their homes because of organized violence, political or religious persecution, or rising ethnic tensions are often exposed to events that place great stress upon their psychological development. These children commonly witness and are subject to extreme violence, lose attachment figures because of family separations or bereavement and invariably leave familiar home and cultural surroundings with resultant disruption to their education and peer relationships. This can lead to different effects on children depending on the nature of their particular experiences, their environment and ongoing support as well as their personal characteristics. Some continue to develop on their pre-existing trajectory, showing remarkable resilience and capacity to survive or even thrive in the face of adversity (Tol *et al.*, 2013). Others increasingly struggle with psychological difficulties under the weight of negative events and circumstances.

There is a misconception that potentially traumatic events are confined to displaced peoples' experiences in their homeland. However, these are often only the beginning of a chain of adverse events. Migration journeys and post-migration experiences are often sources of further distressing occurrences. Achieving settled status in a safe location may take years, or may never be achieved, depending on the legal frameworks and political stability of the resettlement location. During this period and beyond, displaced children and families must make new peer and neighborhood relationships, manage changes in familial roles and master a new language and cultural environment. In high-income countries, they must simultaneously negotiate the asylum processing systems and welfare agencies; in low-resource settings, flight may be followed by years of struggle to meet basic survival needs amid eruptions of organized violence and gender or ethnicity-based attacks. The serious

consequences of cumulative adversity for children's mental health have long been established (Rutter, 1999).

Refugee, asylum seeking, and internally displaced children and adolescents are therefore a group of major concern. In addition, an understanding of the way in which their experiences influence them has the potential to contribute to our knowledge of psychological development. Studying the interplay of the many factors highlighted earlier can elucidate processes underlying resilience as well as psychopathology and help focus on potential areas of intervention (see Chapter 27). In this chapter, some background information on these populations is provided, followed by discussion of particular risk and protective factors for psychopathology, highlighting important studies. Finally, there will be a focus on interventions highlighting some that have been evaluated. It should be noted that interventions are important to consider at all levels—individual, family, school, community, and societal.

In 2011, approximately 16 million children, almost half of the total global population of refugees and people in refugee-like situations, were displaced from their homes (UNHCR, 2011). The variation between refugees' background circumstances, country-of-origin, country-of-resettlement, culture and experiences is so great that it should not be assumed that they are a homogeneous group. There are, however, key elements that are almost universally experienced by refugees: loss, uncertainty, fear, and discrimination. Many experience family and community disruption. It is common for the asylum process to last several years after arrival in the country of resettlement. Financial support for asylum-seekers is typically low even in high-income countries, and many report difficulties in accessing services to which they are legally entitled; those in low and middle-income countries (LMIC) are not uncommonly in situations of humanitarian crisis.

For those internally displaced, or displaced to neighboring countries, local tensions and economic circumstances may necessitate a series of moves, which means that the children may experience repeated adversity and instability. Many have to live in refugee camps and the instability and greater experience of cumulative adverse events appear to place children in these situations at particularly high risk of psychological difficulty (Reed *et al.*, 2012). Hereafter, the general term “forcibly displaced children” will be used to encompass this population, unless specifically referring to a subgroup.

Research with forcibly displaced children has largely focused on the minority who have resettled in high-income countries (Fazel *et al.*, 2012). There are many challenges to conducting research with refugee populations, especially those living in LMICs including the need for cultural and linguistic adaptation of measures, and culturally differing models of conceptualizing adverse events (Bhui *et al.*, 2003). Moreover, studies of interventions for displaced populations have been hampered by a number of methodological issues (Nickerson *et al.*, 2011). These include small sample sizes, lack of post-treatment and long-term follow-up assessments, a lack of random assignment, the absence of appropriate control conditions or interventions and little treatment manualization. Therefore, only a small number of interventions have been adequately evaluated and those that have been evaluated have shown small to moderate effect sizes. While many of the interventions have had good face validity, these difficulties have limited the conclusions that can be drawn about the best way forward.

Definition of terms and the global refugee situation

People who have moved away from their home locality owing to persecution or organized violence are described as “forcibly displaced” and their situation is often exacerbated by the pressures of extreme poverty or environmental challenges. Those moving within their own national borders are described as “internally displaced.” This term is also used for people who have moved owing to natural disasters or severe economic hardship, but in this chapter we use it with reference to those fleeing organized violence. Those who migrate to a different country to escape persecution are typically described by the broad term “refugees,” although in many countries “refugee” has a more specific legal meaning denoting someone who has applied for and been granted political asylum. Hence refugees in these contexts have long-term or permanent rights of residence in the host country. An “asylum seeker” is someone who has applied for but not yet been granted refugee status by the host country. A “failed asylum seeker” is someone who has not been successful in their asylum application and, in many countries, has limited access to health or social care, employment or training, state-funded accommodation, financial support, or family reunification. Moreover, they may be at risk of forcible return to their country-of-origin. The 1951 UN Refugee Convention gave the original classification of a refugee (UNHCR, 1951)

and although this definition is now potentially limited (Quinn, 2011), its principle of protection remains for those whose home countries offer limited protection or who are at risk of torture.

More children and adolescents are internally displaced than are displaced across national borders. Of the latter, most remain in front-line states close to their country of origin. The vast majority of the world’s forcibly displaced populations are, therefore, displaced from one LMIC to other nearby LMICs.

Unaccompanied and separated children are of particular concern as they are under 18 years, living outside their country of origin and separated from their parents or primary caregivers. Some may be totally alone while others may be living with extended family members. All such separated children are entitled to international protection under a broad range of international and regional legal instruments (Hancilova & Knauder, 2011). However, in practice, they can be subject to conflicting policy agendas: the protection of children and children’s rights versus the enforcement of immigration control (Sigona & Hughes, 2012). Despite often experiencing potentially traumatic events in their countries of origin as well as poverty and disrupted education, many experience further harrowing events, abuse and hardship in their journeys to new countries and then have to settle and survive in a new country. Throughout, they lack the physical and psychological support of a trusted adult and this can render them particularly vulnerable. They can fall prey to victimization and trafficking for sexual or labour exploitation (Becker-Blease *et al.*, 2010; Hancilova & Knauder, 2011).

Over the past decade, countries, especially those in the European Union, have been placing increasingly restrictive measures to prevent displaced populations from making asylum claims. Of particular concern is the use of immigration detention facilities that have so far been documented in 60 countries across the globe, both high-income and LMIC (Global Detention Project, 2013, Fazel *et al.*, 2014). Children and adolescents can be detained in many countries for variable lengths of time. In addition, in some countries, children can be separated from their parents when parents are placed in immigration detention.

Prevalence of psychiatric disorder

The main studies that have explored psychiatric morbidity in forcibly displaced populations have focused on the disorders of PTSD, depression and anxiety disorders. Studies have typically (Tousignant *et al.*, 1999; Fazel *et al.*, 2005; Bronstein *et al.*, 2013), although not universally (Rousseau *et al.*, 2000) shown, that forcibly displaced children have substantially higher rates of psychiatric disorder than host populations. This higher prevalence has been demonstrated in systematic reviews for PTSD (Fazel *et al.*, 2005), depression (Bronstein *et al.*, 2013) and anxiety (Bronstein *et al.*, 2013). The range of prevalence estimates for any of these disorders is variable between studies. Part of this variation reflects genuine differences in the balance

of risk and protective factors between the populations being studied, as well as methodological differences between studies.

The prevalence estimates for PTSD in forcibly displaced children show wide variation. A systematic review of PTSD in refugee children (Fazel *et al.*, 2005), which excluded self-report questionnaire-based studies, showed a relatively narrow range of 7–17% across the eligible studies. Estimates of 10–25% are common in studies of children displaced to relatively safe high-income settings, those for internally displaced children in LMICs tend to be higher; for example, a study in a camp for internally displaced persons (IDP) in Darfur showed a PTSD prevalence of 75% in adolescents (Hasanović *et al.*, 2006; Morgos *et al.*, 2007). PTSD in forcibly displaced children is also potentially different to that more typically observed in other populations. This is primarily because they might have been subjected to multiple traumatic events that could be different in nature and in the context they were experienced. For example, a child might witness the death of a parent in their home country, followed by exposure to long and frightening migration journeys, possibly unaccompanied. These children might live without the support of their primary caregiver or with caregivers suffering from their own psychological disorders. All are living in a new country and culture where access to services, if these services exist, might be difficult. Moreover, these factors will have a potential impact on the presentation and treatment of other psychological disorders, such as depression and anxiety.

Estimates of depression typically fall in the range of 5–30% (Servan-Schreiber *et al.*, 1998; Tousignant *et al.*, 1999; Hasanović *et al.*, 2006), again tending toward higher proportions in refugee camp situations (Morgos *et al.*, 2007). Estimates for anxiety range from 10–30% (Tousignant *et al.*, 1999; Bronstein *et al.*, 2013). For depression and anxiety, as for PTSD, there is a relative dearth of high quality evidence. There are fewer studies reporting on other psychiatric symptoms, but a study of psychotic adolescents in in-patient units across London reported an over-representation of black African refugees (Tolmac & Hodes, 2004).

These disorders are also likely to be prevalent in any accompanying parents or caregivers (Hollifield *et al.*, 2002; De Jong *et al.*, 2003; Steel *et al.*, 2009). Parental disorders might impact on their children's development (see Chapter 28). A systematic review of 181 studies of adults who had experienced conflict and displacement indicated a weighted prevalence of over 30% for both depression and for PTSD (Steel *et al.*, 2009). Given the dual challenges of socioeconomic adversity and parental psychological difficulties, it is unsurprising that the children of forcibly displaced parents born after arrival in the country of settlement may also be at elevated risk of a range of conditions, including PTSD, depression and psychosis (Sigal and Weinfeld, 2001; Rutter, 2013).

In summary (Table 44.1), although studies commonly find forcibly displaced children and adolescents to be at increased risk of PTSD, depression, and anxiety, there is little evidence to suggest a significantly increased risk of other conditions,

such as conduct problems or substance misuse (Sack *et al.*, 1994; Tousignant *et al.*, 1999). In fact, some studies suggest fewer behavioral problems in forcibly displaced families, citing a range of explanatory factors including being involved in a meaningful struggle, respect for one's cultural background and sensitivity to parents' difficulties (Sack *et al.*, 1986; Rousseau and Drapeau, 2003).

Risk and resilience in young refugees

Although forcibly displaced children and families commonly experience a large number of distressing events, it is important not to make assumptions as to the impact of such events on the individual, based on the apparently "objective" severity or number of events. There is huge heterogeneity in individuals' responses to different stressors and adversity (Rutter, 2013). Whether or not they lead to prolonged adverse psychological consequences for the individual depends on a range of factors and on cultural differences in understanding and responding to adversity (Barber, 2013). These include the pre- and post-event context, ascribed meaning and appraisals, prior mental health, prior and subsequent adversity and distressing events, genetic influences and parental and social support (Miller and Rasmussen, 2010; Reed *et al.*, 2012; Tol *et al.*, 2013).

Those working with these children and adolescents must remain alert to all the standard risk factors for psychopathology in children; the unusual events experienced by displaced families should not distract clinicians from other significant past and present risks to children's mental health. On-going serious risks that therefore need to be assessed include child maltreatment, parental conflict and domestic violence, community violence, racially based discrimination, poverty and bullying, as studies have shown a possible increase in incidence in many of these for forcibly displaced populations (Catani *et al.*, 2010; Layne *et al.*, 2010).

The societal context

Post-migration factors, many of which are modifiable, have been shown to alter the risk of developing psychological problems in forcibly displaced children and adolescents (Fazel *et al.*, 2012; Reed *et al.*, 2012). While exile and repatriation are no doubt stressful experiences for children, remaining in a conflict situation without displacement is equally, if not more, detrimental to psychological well-being. In addition, living in refugee camps (Thabet and Vostanis, 1998; Izutsu *et al.*, 2005) or within immigration detention facilities can place psychological health at serious risk (Rothe *et al.*, 2002; Lorek *et al.*, 2009). Detention facilities may expose children to witnessing and experiencing additional potentially traumatic events, including fires, rioting, violence and self-harm attempts by others (Mares *et al.*, 2002), and furthermore may have a serious impact upon parental mental health, impairing the capacity to sensitively parent children with increased needs.

Table 44.1 Some illustrative studies of the prevalence and risk factors for psychiatric disorder in forcibly displaced children and young people.

Study	Year	Sample	Findings
<i>LMIC studies</i>			
Morgos (2007)	2007	331 internally displaced children in camps in southern Darfur	75% met criteria for PTSD, 38% for depression
Mels (2010)	2010	819 adolescents of age 13–21 in the eastern Democratic Republic of Congo (217 internally displaced and 496 previously displaced returnees)	Internally displaced adolescents reported the highest scores for post traumatic symptoms
Paardekooper <i>et al.</i> (1999)	1999	316 Sudanese refugees in Uganda compared to 80 local Ugandan children	Sudanese refugee children reported significantly more depressive and post traumatic symptoms and behavioral difficulties than local children
<i>High-income country studies</i>			
Nielsen (2008)	2008	246 children in Danish detention centers	Children with at least 4 relocations had worse mental health
Sujoldzic (2006)	2006	499 adolescent Bosnian refugees in Croatia and Austria compared to 359 internally displaced Bosnians and 424 non-displaced Bosnians	Girls had worse functioning than boys and were more likely to suffer anxiety and depression; discrimination and poor school and neighborhood connectedness was associated with worse functioning, whereas religious commitment was associated with better functioning
<i>Studies of unaccompanied asylum-seeking children (UASC)</i>			
Bronstein <i>et al.</i> (2013)	2012	222 Afghan unaccompanied asylum seeking adolescents, age 13–17	35% scored above cut-offs for anxiety and 23% for depression
Bean <i>et al.</i> (2007a)	2007	582 unaccompanied refugee children from 48 countries	Psychological distress was higher with increasing age and girls had higher scores for post traumatic and internalizing symptoms: unaccompanied young people had experienced twice as many post traumatic events as accompanied young people

Prolonged insecure asylum status and residential instability are disorientating and distressing for parents and children alike (Bean *et al.*, 2007b; Nielsen *et al.*, 2008), and often give rise to secondary adversities such as parental unemployment, financial strain, social isolation and limited engagement with education or community life. Government policies differ greatly between countries with regards to the detention of child and adult asylum seekers, and the time-frame for the resolution of asylum claims. Attempts to minimize the duration of uncertainty and residential disruption of asylum-seeking families, to avoid the detention of children, their parents and pregnant women, and to abolish the separation of parents and children for the purposes of detaining adults in a family, are important safeguards to prevent deterioration in children's mental health (Fazel *et al.*, 2012).

Consideration must also be given to the impact of the relative privacy and security of accommodation on mental health (Ajduković and Ajduković, 1993; Geltman *et al.*, 2005). For unaccompanied young people, accommodation in centers is associated with poorer functioning than independent accommodation or foster care (Derluyn and Broekaert, 2007). More supported living arrangements are associated with better psychological outcomes (Bean *et al.*, 2007a; Derluyn and Broekaert, 2007; Hodes *et al.*, 2008). Foster care raises additional challenges

but same-ethnicity placements appear to confer a protective effect (Porte & Torney-Purta, 1987; Geltman *et al.*, 2005).

The community context

Higher levels of perceived acceptance and connectedness within a community and low levels of racial discrimination have been associated with lower levels of psychological problems (Sujoldžić *et al.*, 2006; Montgomery and Foldspang, 2008). The issue of acculturation has received considerable attention; the construct is difficult to measure, and usually reduced to linguistic competency and time since migration. Overall, the ability to integrate into the host society and acquire the local language while maintaining a sense of one's cultural identity emerges as somewhat protective (Fazel *et al.*, 2012). The importance of the formation and maintenance of social networks within the same ethnic group and some form of religious belief, as well as a sense of connectedness to the neighborhood and school, are linked to positive mental health outcomes (Sujoldžić *et al.*, 2006; Kia-Keating and Ellis, 2007).

Children and young people with friendships have fewer psychological difficulties (Almqvist and Brandell-Forsberg, 1997; Berthold, 2000) and parental support networks also have an indirect positive impact on children (Ekblad, 1993). In some cultural contexts, a large same-ethnicity network may

have an adverse rather than protective effect, possibly related to increased social obligations and expectations (Rousseau *et al.*, 1998).

The family context

There is increasing evidence for the importance of good parental functioning in protecting the mental health of young people who have experienced forced displacement (Catani *et al.*, 2010; Walker *et al.*, 2011; Tol *et al.*, 2013) and a large body of work outside refugee studies also attests to the importance of remaining with family or steadfast caregivers. When we consider young people who arrive with their families, the family may appear to be one “constant” in a maelstrom of change and can cushion against external adversities. However, the dramatic changes and shifts that may occur in forced displacement can cause disruptions to family structure and function that can compromise the adequacy of parental caregiving (Walker *et al.*, 2011). At the very time when children are most in need of sensitive parental care to buffer them against the adverse events around them, parents themselves are distressed, preoccupied and over-burdened with the struggle for basic survival needs.

It is, however, well-demonstrated that the presence of parents is nonetheless protective and improves outcome; unaccompanied young people are known to be at increased risk not only of a higher toll of potentially traumatic events during their migration journey, but also of a higher likelihood of significant psychological difficulty after arrival (Hodes *et al.*, 2008; Thabet *et al.*, 2008).

The individual context

The cumulative number of pre-migration adverse events is the strongest predictor of psychological disturbance (Fazel *et al.*, 2012; Reed *et al.*, 2012). These risks are higher with events of greater personal threat (Angel *et al.*, 2001; Geltman *et al.*, 2005). Different patterns of exposure by gender are observed in different contexts, for example, the use of rape as a weapon against girls in refugee camps (Crisp, 2000), or the targeted recruitment of boys as child soldiers (Betancourt *et al.*, 2010b), and stigma and discrimination resulting from these particular types of exposure are major barriers to recovery and social reintegration (Betancourt *et al.*, 2010a). Exposure to post-migration violence is also associated with increased risk (Berthold, 1999). Children who have experienced conflict also experience a wide range of non-conflict related potentially traumatic events, which they may identify as equally or more traumatic, including experiences of domestic and community violence (Panter-Brick *et al.*, 2009).

With regard to gender, girls generally have a higher risk of poor mental health outcomes, especially after puberty (Sujoldžić *et al.*, 2006; Derluyn and Broekaert, 2007; Fazel *et al.*, 2012), in keeping with childhood patterns of anxiety, depressive, and post-traumatic symptoms in the general population (Ford *et al.*, 2003). No clear age effects have emerged from the available studies (Reed *et al.*, 2012; Fazel *et al.*, 2012), although studies from countries where a final asylum decision is made at a specific age (typically

around 18 years) commonly show a deterioration in later adolescence, reflecting the approach of this decision point (Bean *et al.*, 2007a, b).

Assessment

Clinicians may be part of a targeted service or only examine such children infrequently. The assessment of such children needs to be carried out with particular sensitivity. In areas with high forcibly displaced populations, there is scope for a group of professionals to work together and develop expertise in advocacy and in addressing other educational and community needs. A careful explanation as to the purposes of the assessment and wish to help the child is important and an initial focus on the here-and-now and less distressing issues can be helpful. As a result of their experiences, such children may be wary of anybody who appears to be in authority, especially if they are asking questions about their past. Furthermore, many may have difficulty talking about past traumatic experiences especially if, for example, it has involved witnessing the killing of loved ones and the experience of torture. The assessment will need to proceed cautiously and at a pace that the child can manage. The assessment needs to include the range of past and current experiences. Figure 44.1 illustrates some of the specific questions that may need to be considered and their relationship to the child's migration experience.

Children and adolescents who have undergone forced displacement will have experienced life in at least two countries. The assessment needs to include positive strengths and qualities, temperament, coping skills and adaptability, language, ethnic and religious identity, and, for accompanied children, key family relationships. Assessment can, therefore, be particularly complex. For simplicity, this is often considered in pre-migration, peri-migration (journey from the country of origin to the new country, including residence in camps) and post-migration phases. Many children can have more complex experiences, including multiple displacements and returns within their own or other countries, being born in camps or in a country of transit, or being held in immigration detention facilities.

Clinicians should expect to obtain information slowly and patchily. In addition, careful attention must be given to risk assessment and child protection issues, particularly for unaccompanied minors. Time should also be allowed for liaison with other statutory and non-statutory agencies supporting the families and young person, in particular those dealing with accommodation, care needs and legal issues around asylum claims.

Other complexities of assessment include:

- 1 Language and cultural differences. As with any cross-cultural assessment, it is important to gain an understanding of the cultural influence on concepts of: physical and psychological health and illness; the meaning of the distressing events experienced; any stigma attached to the events experienced, resultant symptoms or attitudes to accessing services; the acceptability of treatments and the use of alternative healing practitioners or preparations. Moreover, it should be borne in mind

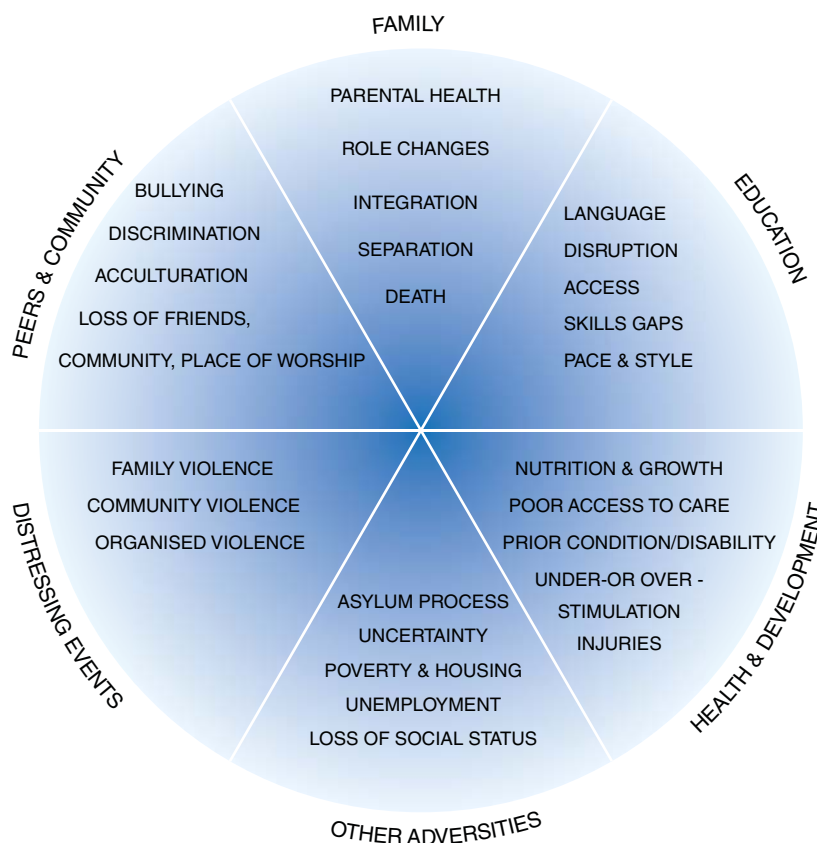

Figure 44.1 Assessment considerations for forcibly displaced children. Some of the factors described apply only at one phase of the migration process, but it is important to remember that most adverse exposures, such as violence and multiple relocation, can be experienced at any stage of migration.

that family members and young people may be at very different stages of linguistic and cultural adaptation to the host society and may view their cultural identity differently.

- 2 Use of interpreters. Ensuring the acceptability of a particular interpreter and trying to keep the same interpreter from session to session is ideal. It is important to discuss confidentiality issues with the interpreter before a session, as interpreters might not have health training. It is also essential to have time with the interpreter alone at the end of potentially distressing sessions to discuss confidentiality and ensure that the session has not raised any difficult issues or memories for the interpreter, who might themselves have come from a conflict-affected area. Interpreters from smaller communities or language groups might present difficulties as they can often interpret for the children in multiple contexts. Sharing a language might be indicative of that person coming from the same region but potentially from the “other” side, placing a child at perceived or real risk if the interpreter remains in the session and privy to personal information.
- 3 Limited availability of information regarding the child’s development and current risks, either because of absence of primary caregivers or due to communication difficulties.
- 4 Misinformation about immigration processes. The children and their families might have been told, by people traffickers

and others who helped them enter the country, not to share certain aspects of their background and history with immigration and care organizations. The reasons such people give are often incorrect, potentially exposing them to more difficulties with post-migration authorities.

- 5 Lack of understanding about the role of the different health and social care agencies involved by children and their families.
- 6 Use by families of other potential mental health providers including traditional healers and religious leaders.

Interventions

Forcibly displaced children encounter many barriers in accessing health care. The development of interventions to address the needs of forcibly displaced children and adolescents needs to be twofold. General multimodal interventions that concurrently address a number of issues in the environment and social networks need to take place alongside targeted interventions for those with more specific trauma-related needs (Miller and Rasmussen, 2010; Nickerson *et al.*, 2011). This dual strategy approach is supported by a number of reviews exploring interventions for refugee children (Tyrer and Fazel,

2014), war-affected children (Betancourt and Williams, 2008; Jordans *et al.*, 2009) and adults (Nickerson *et al.*, 2011). The available evidence on interventions for forcibly displaced children and adolescents is, however, limited, so general principles and interventions of note are explored in the following sections (see Chapters 36 and 59). There is a scarcity of rigorous studies and the interventions that have been evaluated thus far are different from each other, both in terms of their settings and their specific findings (Jordans, 2009). In the following section, we summarize the key components of these interventions and highlight the areas that are most important.

In LMICs, the resource constraints are considerable and mental health services usually fall far below need, especially when compared to other health care provisions (Patel *et al.*, 2007a). Interventions might need to be delivered in refugee camps and the stigma of having a mental health problem can often impede help-seeking behaviors. Multimodal interventions integrated into other systems of care, such as women's health or primary care, might be more acceptable in these settings, where mental health resources are scarce. Moreover, considerable barriers exist within high-income settings. These include resources, linguistic and cultural barriers, concerns about stigma and confidentiality, and beliefs that having a psychological problem might negatively impact on asylum applications.

Trauma-focused interventions

The best evidence available to date is for trauma-focused interventions. These have mainly been studied when delivered on an individual basis although some interventions have used groups. The settings have ranged from specialized mental health services to schools and refugee camps. These findings are in line with the overall evidence for treatment of PTSD where exposure to the "event" or events is a key feature in effective psychological treatments (see Chapter 59). The majority of studies have been conducted in high-income countries where the best evidence for efficacy lies with cognitive behavioral therapy (CBT), in particular Trauma-Focused CBT (Cohen *et al.*, 2000; Taylor and Chemtob, 2004; Fremont, 2004; Silverman *et al.*, 2008; Tol *et al.*, 2008). In this treatment modality, the fear conditioning is treated as a key etiological agent alongside disturbances in memory processing and cognitive appraisal (Nickerson *et al.*, 2011). CBT facilitates the extinction of this learning by processing the traumatic memories and altering maladaptive appraisals of threat and overcoming avoidance behaviors. For children and adolescents useful techniques include cognitive restructuring, relaxation training, anger management training, teaching coping skills, and grief management (Fremont, 2004).

Other therapeutic treatments for which there is increasing evidence of effectiveness include Narrative Exposure Therapy (NET) (Robjant and Fazel, 2010) and a range of creative-expressive techniques. There is evidence for Eye-Movement Desensitization and Reprocessing in non-refugee children with PTSD (Cloitre, 2009). Studies exploring the use of pharmacotherapy in this population are lacking but given the high

prevalence of depression and anxiety, medication may be an adjunct or alternative treatment to psychological therapies and other interventions, depending on treatment availability including supervision, patient preference, comorbidity, and symptom severity.

Multimodal interventions

Multimodal interventions aim to concurrently address issues of psychological functioning, social and cultural adaptation, physical health and ongoing psychosocial difficulties (Nickerson *et al.*, 2011). Although the evidence supporting their use is limited, it is relevant that such programmes offer a range of interventions because forcibly displaced populations can be exposed to diverse stressors and challenges leading to a complex array of psychological reactions.

At the societal level, these interventions aim to influence the wider environment through advocating for more services and stable housing, promoting language proficiency, improving immigration applications, and employment opportunities. The restoration of an enabling/supportive environment for the young person and their family and friends is likely to be key to stabilizing their psychological health (Betancourt and Williams, 2008; Jordans *et al.*, 2009). As Miller points out, a focus on healing the effects of previously experienced war trauma may appear valueless to a child who is currently being beaten or sexually abused at home or in the community (Miller and Rasmussen, 2010) or whose basic survival needs are a day-to-day struggle (Mels *et al.*, 2010).

Multimodal interventions have also tried to address community and school-based needs. Achieving in school, with regard to both education and peer relationships is a key determinant of success and future mental health (Viner *et al.*, 2012). Refugee children can experience specific problems fitting into school because of language and cultural differences as well as bullying and discrimination (Kia-Keating and Ellis, 2007). A systematic review of community and school interventions for forcibly displaced children and adolescents (Tyrer and Fazel, 2014) identified 20 studies in total, of which seven were conducted in refugee camp settings and the rest were mainly school-based interventions in high-income countries. The interventions were a combination of individual, family and group, or classroom interventions and the multimodal interventions used an array of creative art techniques, often in combination with trauma-focused interventions.

Interventions should aim to help strengthen families (Walker *et al.*, 2011). This is because a consistent finding across studies is the importance of parental support for children's mental health (Tol *et al.*, 2013). The studies to elucidate how best this can be performed are limited, but some studies have offered support to parents and siblings and others have focused on the parent-child interaction in therapy. Restoration of social support networks for children and their families is another important aspect of multimodal interventions more generally (Jordans *et al.*, 2010). Although some studies have tried to

address these in post-conflict settings, the studies on forcibly displaced children and adolescents are still limited. Moreover, the importance of harnessing cultural resources and extended kin networks are likely to be important (Tingvold *et al.*, 2012).

In summary, the individual psychological needs of these children require addressing using the most effective available interventions (Table 44.2). Moreover, the overall needs of this population need to be considered. If housing or educational needs are not being addressed, for example, if they are living in an unhappy foster home or if they have additional learning difficulties, then a clinical service might need to work to assist all these areas. For the young person, having these different services brought under the umbrella or oversight of one service might be very helpful and so ensuring flexibility in response is likely to be of greatest overall benefit. In addition, many young people find their therapists getting involved in their asylum application supportive and important.

Course and long-term outcomes for young refugees

A 9-year follow-up study of 131 refugees in Denmark (mean age 15.3 years) showed that the long-term effects of pre-migration trauma are mediated by risk and protective factors at the individual, family, and community level (Montgomery and Foldspang, 2008; Montgomery, 2010). Aspects of social life in Denmark and the stresses experienced in exile were more strongly predictive of psychological problems 8–9 years after arrival than traumatic experiences before arrival, highlighting the importance of the post-migration environment. Sack and colleagues' 12-year follow-up study of Cambodian adolescents indicated that post-migration stressors were particularly associated with depression, whereas post-traumatic stress was more closely related to pre-migration events (Sack *et al.*, 1993; Sack *et al.*, 1994). Bean and colleagues noted strong continuity and ongoing high levels of psychopathology at 1-year follow-up in a cohort of 582 unaccompanied minors (Bean *et al.*, 2007b).

There are a number of studies of note from adult populations that can also inform our understanding of the long-term outcomes in children and adolescents exposed to forced displacement or war experiences. A study of adults in four post-conflict settings (Ethiopia, Algeria, Cambodia, and Gaza)

highlighted the range of PTSD prevalence rates across contexts with a diversity of risk factors (De Jong *et al.*, 2001; De Jong *et al.*, 2003). In addition, the study demonstrated that conflict events after age 12 were particularly likely to have an adverse effect, and this could be because of developmental, cognitive, or environmental influences. Another study of Cambodian refugees interviewed two decades after resettlement in the United States of America showed how prolonged the psychological effects of forced displacement can be as 62% fulfilled diagnostic criteria for PTSD and 51% for depression (Marshall *et al.*, 2005). Those who had been displaced in adolescence had better psychological health but these results highlight how both children and their parents can be affected by their experiences for considerable periods of time.

There is limited knowledge regarding the intergenerational repercussions of traumatic events, although second generation refugee children had worse psychological outcomes in a study in rural South Africa (Cortina *et al.*, 2013) and there is evidence from a registry-based study that second-generation refugees have an increased risk of hospital admission for psychotic illness, whereas there was no elevated risk for second generation labor migrants (Rutter, 2013).

Conclusions

The psychological adjustment of a child or adolescent who has been forcibly displaced because of organized violence is likely to be influenced by a number of different factors that may be inter-related or independent. These include the severity of exposure to any potentially traumatic experiences, previous and current family support, the degree and duration of disruption to their life and the amount of social disorganization that ensued and still exists in their environment (Pine *et al.*, 2005). Therefore, when trying to meet the mental health needs of these children, interventions to address distressing memories and family dynamics must take place alongside attempts to address the wider local and regional social, economic, and educational systems disrupted by war. This can seem like an impossible task for the LMIC countries, in which the majority of forcibly displaced children live, given their overall lack of mental health services, especially for young people (Patel *et al.*, 2007b; Chapter 16).

Table 44.2 Examples of randomized controlled trials.

Intervention domain	Study	Year	Sample	Intervention	Findings
Individual therapy	Ertl (2011)	2011	85 Ugandan former child soldiers	Narrative Exposure Therapy-8 sessions conducted in camps	Improvements in PTSD symptoms
School-based	Rousseau (2005)	2005	138 immigrant children in Canada	Creative expression classroom programme over 12 weeks	Beneficial effects on self-esteem
Community-based	Bolton (2007)	2007	Ugandan internally displaced children living in refugee camps	Group Interpersonal Therapy (IPT-G)-16 sessions conducted in camps	IPT-G helped reduce levels of depression, especially in girls and older children

Moreover, while education and employment are likely to be key factors for their long-term mental health (Viner *et al.*, 2012), access to these is a further challenge in LMIC settings.

The main focus of research now lies in the development of appropriate and sustainable interventions (Tol *et al.*, 2009). For LMICs, interventions developed in high-income settings are unlikely to be generalizable to these environments (De Jong *et al.*, 2001). A major development involves understanding how to adapt interventions delivered by clinical health specialists so that they may be carried out by lay or generic workers with limited training (Tol *et al.*, 2012; see Chapter 48). This has been achieved in some studies for adult refugee populations and for children in conflict settings (Robjant & Fazel, 2010). Further research should identify the core skills that are necessary, how training should be conducted and the groups most likely to benefit from such interventions. There is some emerging evidence of differential gender effects, with girls possibly benefiting more from certain interventions (Bolton *et al.*, 2007); research should also seek to identify how to modify interventions to optimize outcomes across all groups. It is also vital that interventions do not undermine natural recovery processes in individuals, families, or communities (Tol *et al.*, 2012). It may be necessary to adapt interventions to make them more culturally sensitive in areas with relatively homogeneous displaced populations, which might be more likely in LMICs. However, in high-income settings, where refugee communities can be highly heterogeneous, they might instead be targeted to the local context rather than a specific cultural group, for example, improving school integration and addressing bullying in a locality where the refugee community suffers discrimination and stigmatization.

Regardless of the setting, learning how best to harness cultural, community, and family resources is essential. Certain policies and practices are overtly detrimental to mental health (Viner *et al.*, 2012) and need to be prevented, such as immigration detention. There are also likely to be benefits of integrating mental health services with other youth health and welfare expertise (Patel *et al.*, 2007b) and delivering a multi-layered care package (Jordans *et al.*, 2010).

While developing emotionally, socially, intellectually, and physically, forcibly displaced children and adolescents face disruption to their family structure, accommodation, cultural and linguistic environment, friendships, and education. Many also suffer bereavements or disappearance of family or friends and struggle with intrusive memories of violence. Despite this, many children nonetheless thrive and develop well, and there is much to be learnt from the processes and factors that promote positive outcomes after extreme adversity. Although there has been encouraging progress in research into refugee mental health, many potentially modifiable factors continue to impact adversely upon children and families' health even after arrival in safe, stable, and well-resourced resettlement countries. There is a clear role for mental health professionals to address barriers to accessing health care, improve the cultural sensitivity and acceptability of services, challenge stigma and prejudice,

develop effective interventions and modes of service delivery and advocate for refugees' mental health when local or national policy and practice endangers the fragile balance between risk and resilience.

CHAPTER 45

Pediatric consultation and psychiatric aspects of somatic disease

Elizabeth Pinsky¹, Paula K. Rauch² and Annah N. Abrams¹

¹Child and Adolescent Psychiatry Consultation Service, Massachusetts General Hospital, Boston, MA, USA

²Child and Adolescent Psychiatry Consultation Service and Cancer Center Parenting Program, Massachusetts General Hospital, Boston, MA, USA

Introduction

“Pediatric consultation” or “pediatric consultation-liaison” care refer to child psychiatrists or child psychologists who are mental health professionals providing psychological and/or psychiatric care to medically ill children, with special attention to biological, psychological, and social mediators of well-being. In other contexts, “consultation” can refer to school (see Chapter 42) or forensic (see Chapter 49) settings. In this chapter, we refer to the task of the “mental health consultant” as assessment and management of the psychiatric status of the medically ill child, most often in a medical hospital environment.

Mental health consultants assess (i) children with primary psychiatric illnesses leading to medical conditions, (ii) psychiatric manifestations of medical illnesses or treatments, (iii) adjustment to a chronic or life threatening illness, and (iv) differential diagnosis of psycho somatic illness. In addition, the consultant’s scope may include working with anxious or challenging parents, providing liaison work with ward staff, offering didactic lectures for medical staff or parents, and advocating with hospital leadership to develop more psychologically attuned standard practices.

The medically ill child’s phase of development, temperament, social and cultural context, type and stage of illness, family dynamics, and level of pain and anxiety are among the multitude of contributing factors determining the complexity of clinical care and research in the pediatric consultation population.

History

Adult consultation psychiatry arose in general hospitals during the 1930s, with the recognition that a mind-body dichotomy

was an inadequate approach to provide quality medical care and that psychological issues have an impact on medical illness and treatment (Ortiz, 1997). As the integral role of psychological factors was established in adult medical care, similar attention was focused on the needs of children (Work, 1989). While the literature continues to demonstrate benefits of collaboration between child psychiatrists and pediatric staff (Carter *et al.*, 2003; Fritz, 2003), consultation psychiatry by no means exists in every pediatric medical and surgical setting today. Throughout Europe consultation resources are limited, and they are virtually unavailable in many low- and middle-income countries.

In part this is because consultation services require institutional support, especially for otherwise unreimbursed activities such as pediatric and psychiatric clinical collaborations, comprehensive evaluations, and interdisciplinary team meetings. In addition, as the medical care of children, like adults, is moving toward shorter hospital stays and greater utilization of outpatient settings for treatment of chronic and life threatening illness, mental health consultants will be called upon to shift their availability to encompass these outpatient settings.

Consultation service models

Consultation service models will be determined by the size of the patient group served, the illness severity of treatment populations, and the availability of child mental health consultants. In many pediatric medical settings, child psychologists are the primary child mental health consultants with child psychiatrists limited to acting as pediatric psychopharmacologists. Mental health consultants, regardless of their training discipline, need understanding of disease process, medical

management of relevant illnesses, and a comprehensive set of psychological interventions (see Chapter 36), including mind-body techniques.

Consultations can be initiated on a case-by-case basis or by protocol or as a mix of each. In the case-by-case model, the pediatrician requests a consultation after assessing an individual patient, while consultation by protocol systematizes psychiatric consultation for children with certain diagnoses or risk factors. Examples of protocol driven consultation include routine consultation to patients who are candidates for transplant, or have been admitted after suicide attempts, or require hospitalization longer than 2 weeks.

“Liaison” care

Arguably, no consultation to a hospitalized child can be provided effectively without the integral “liaison” component addressing concerns arising from members of the treatment team. Work with medically ill children is rewarding, but it can also arouse powerful feelings of sadness, frustration, and helplessness. Pediatric units may seek input from the consultant to address the emotional challenges experienced by the medical team, assist them in their ability to provide the best care for patients and prevent long-term burn out (Levi *et al.*, 2004; Bateman *et al.*, 2012).

Approach to consultation requests

The first task for the consultant when responding to a request is to understand: *what is the consultation question?* While the consultation question is sometimes clear (e.g., is there underlying psychiatric illness; what is the appropriate disposition for a child admitted with self-harming behavior), often it is obscured by affect between care providers or with the family or patient (e.g., why is this family driving us crazy; why can’t the medical teams agree on treatment goals). The consultant should speak directly with the consulting pediatrician or staff member, listen to the expressed concerns and ask for elaboration about concerns that appear present but not disclosed. It is important to establish realistic goals and to determine acuity for the initial consultation as early as possible and as part of a step-by-step approach to the consultation (Table 45.1).

The pediatrician or subspecialist with whom the family already has a relationship should inform the parents of the decision to obtain a psychiatric consultation. Psychiatric consultation may be presented as part of the diagnostic process, as a way to help the team understand how the child is feeling, or as a response to the challenges that hospitalization has presented. Some parents and children may be uncomfortable with the idea of psychiatric consultation, and yet appreciate the intervention upon finding the child mental health consultant respectful, knowledgeable, and attuned to the needs of the child and family. Other parents will be resistant, reluctantly agree under some pressure from the referring pediatrician, and perhaps remain ambivalent

Table 45.1 Steps to the consultation.

-
1. Consult request
 - Case-by-case or protocol driven
 - Psychiatrist, psychologist, supervised trainee
 2. Discussion with consulting team
 - What is the consultation question?
 - What is the acuity of the request?
 - Who will inform the family of the consultation?
 3. Review of medical data
 - Data specific to the child
 - Information specific to the medical illness
 4. Interview
 - Family and child
 - Collateral data: school, existing treatment team
 5. Mental status examination
 6. Formulation
 - Premorbid medical and psychiatric function
 - Developmental/age specific perspective
 - Illness specific perspective
 7. Presentation of recommendations to team
-

about the benefit of the assessment or come to appreciate its value. Parents who are concerned about stigma around mental health care may be reassured when the consultant is introduced as a member of the multidisciplinary team and a resource for the family to assist their child with adjustment and coping, as opposed to being involved due to concern about psychopathology. For those families who refuse consultation, the consultant may meet with the team in a liaison capacity and assist the team without directly interviewing the child. If the psychiatric consultation is deemed urgent, the pediatrician should seek input from the hospital legal counsel about the appropriate way to proceed within the legal system in which the pediatrician practices.

Prior to meeting with the family and child, the consultant should review relevant medical data, including pediatric and subspecialist notes, laboratory and imaging studies, medication administration reports, and other studies where appropriate. The consultant should also review basic information about any specific medical illness and be familiar with general planned work-up or treatment.

The consultation

Interview of child and family

Depending on the age and circumstances of the child’s condition, the consultant will decide whether to meet with the parents first, the child first, or both together. Meeting with older children without a parent present at some point is usually essential. This allows them to voice private concerns and allows for observation of differences in mental status (including mood and affect) with and without family present. Children under six are often more comfortable meeting with the consultant along with a parent. The parents of young children are likely to want time alone with the consultant to share observations and concerns which are not

appropriate to share in the child's presence. Similarly, many parents of older children will find it easier to be candid about their worries in the absence of the child.

No child can be understood independently of his or her family. In the initial evaluation, it is therefore essential to assess the family's level of functioning and their ability to support the child in the hospital and through the anticipated treatment and outcome. Parental anxiety and distress are associated with a child's psychological adjustment and capacity to cope (Sawyer *et al.*, 1998; Wagner *et al.*, 2003; Palmer *et al.*, 2011). Asking parents to share the history of the current illness, from the first symptoms through to the present hospital stay, allows the consultant to learn about the parents' experience of the medical care. It is helpful to understand the parents' views of past and present medical caregivers as well as their experience of their own role in the child's medical condition. An assessment of the family should include psychiatric history for each parent and the siblings, and questions about the family's past experiences with illness and loss. Helping the parent differentiate the current medical situation from past experiences helps the parent be more attuned to the child's actual needs.

Siblings are often the forgotten sufferers (Alderfer *et al.*, 2010). The sick child is commonly the object of everyone's attention, while siblings often live with disrupted schedules, less attention, and less emotionally available parents. The consultant can model empathy for siblings and help parents with ways of addressing the needs of their well children.

Difficult parents often cannot bear the feelings of helplessness and vent their anger and frustration on hospital staff by being critical and devaluing (Groves & Beresin, 1999). Pediatric hospital staff members may have a harder time working with some parents than the patient. The consultant can help the team understand the family better and feel more empathy for difficult behaviors.

Collateral sources

The consultant should seek information from other members of the treatment team, including nursing staff and child life specialists, who may offer especially valuable observations. After the initial assessment and with permission from the parents or guardian, the consultant may seek input provided by sources outside of the medical arenas such as an outpatient psychotherapist, school professionals, or members of other involved social agencies such as the department of social services, or the court system.

Formulation: premorbid medical and psychiatric functioning

When the consultant is assessing a hospitalized child, the consultant is seeing only "a snap shot" out of the child's life. Some families will be confronting a new diagnosis or change in the prognosis, while others may have had time to develop an ongoing coping strategy in the face of a chronic illness or a lengthy treatment protocol. Assessment should recognize the potential

for wide variation in coping at different points in the unfolding medical experience.

Formulation: conceptions of medical illness across child development

Development is an important lens through which a childhood medical illness can be observed. A full review of the interplay of development and medical illness is beyond the scope of this chapter, but a few key developmental points will be highlighted to illustrate common issues.

Infants and toddlers cannot understand the gravity of a given diagnosis. They live in the moment experiencing the medical condition and treatment according to the physical limitations and discomforts imposed. Infants rely on key caretakers to hold and soothe them and to make the hospital environment feel safe. It is important for the hospital staff to support the infant-parent attachment, and not allow treatments and technologies to interfere with this key emotional milestone. Interventions include supporting breast-feeding mothers and allowing rooming-in by parents.

Very young children (3–6 year olds) are egocentric, that is, they understand all events as occurring in relation to them. They have associative logic, which means that for them any two unrelated things can be understood as if one is causing or explaining the other. The combination of egocentricity and associative logic leads to "magical thinking," the weaving together of fantasy and logic to explain how the young child caused something to happen. In the medical setting, it is frequently the child's misconception that having a "bad illness" means he did something wrong and is being punished. It is helpful to get young children (and often older children as well) to elaborate their understanding of the etiology of their medical conditions to uncover self-blaming misconceptions and correct them.

At this age, children cannot localize a medical condition to a specific body part, so they feel particularly physically vulnerable when ill. Faced with needle sticks, intravenous medication and surgical procedures, they are often fearful. They rely on parents and medical staff to prepare them for procedures so they come to trust that there will not be surprise medical attacks at any moment. The young child is likely to demonstrate the most affect around separations, such as having anxiety about going to sleep at night in his own bed, or wanting a parent to promise to be there when she wakes up from surgery.

Older children (approximately 7–12 years of age) can understand simple, functional explanations of medical conditions. Many will pride themselves on mastering the names of medicines, illness related terminology, and how to use hospital equipment. Children of this age look for simple cause and effect etiologies for illnesses. They can understand viral illnesses being caused by "germs," but are perplexed when there is no clear causal explanation, for example, for why they have cancer without having smoked cigarettes. It is important to explain illness and treatment simply and clearly. In the context

of understanding why a treatment plan is being initiated, the medical staff should seek the child's assent to procedures and treatments. This age group is typically rule-bound, and it is troubling to the child that so often medical illness does not follow "the rules" (e.g., she avoids her asthma triggers and has an asthma attack anyway).

Adolescents (13 and older) generally have abstract thinking and thus are able to understand the chance bad luck of having an uncommon, life threatening, or chronic illness with the same cognitive complexity of an adult. That said, teens often do not have the maturity to incorporate the healthy behaviors that they know that they should engage in, into appropriate changes in lifestyle. Turning cognitive understanding into behavioral change is the common battleground of adolescent and authority figure—parent or physician. Consent should be sought from adolescents who have the cognitive ability to comprehend the purpose of treatment and the ramifications of refusing treatment.

Adolescence is a self-conscious time with the emergence of sexual interests and heightened reliance on peer group norms for style and status. Medical illnesses or treatments that affect appearance are particularly difficult such as becoming cushingoid on steroids or bald with chemotherapy. The medical staff is challenged to find ways to respect the teen's age appropriate wish to be more independent in the face of illness that so often increases dependency.

As children with chronic illnesses live into adulthood, the transition to young adulthood and understanding associated issues becomes relevant. Young adults are negotiating intimate relationships, career decisions, independence from parents, and sometimes relocation or parenthood. One challenge that the treatment team and patient may face is whether to transition care from a pediatric setting into an adult setting, which often necessitates a new treatment team. This is a particularly vulnerable time as adolescents are at risk of medication nonadherence increase and of loss to follow-up (Shemesh *et al.*, 2010; Garvey *et al.*, 2012). Some patients may prefer to be on an adult ward or waiting room, but may find it very difficult to leave lifelong caretakers and the pediatric model of care.

Formulation: illness-specific medical perspective

Each medical condition carries its own specific challenges. When the consultant is familiar with common frustrations or limitations imposed by a particular medical illness, they have credibility with a child or parent as they relate what is hardest for them. Routine consultation to the same pediatric unit leads to the consultant becoming familiar with technology, treatment protocols, and terminology, all of which makes it easier for the child and family to tell their medical story and feel understood.

Mental status examination in the hospitalized or medically ill child

Hospitalized children have many reasons to have an altered mental status including delirium, central nervous system (CNS)

changes secondary to medical conditions, effects of medications, and trauma. A formal mental status examination should be part of the medical record including observations of appearance, motor function, speech, mood, affect, thought, suicidal ideation, memory, and cognition.

Medically ill children may be developmentally delayed or emotionally immature. It is helpful for the consultant to integrate the information from the mental status examination and premorbid school and developmental information to assist the medical team in understanding the child's ability to comprehend medical information.

Presenting recommendations to the team

After meeting with the child and family for the initial assessment, the consultant will share observations and recommendations with the referring pediatrician, available team members, and write a note in the hospital record. The consultant should attend to the urgency and time frame in which the referring doctor needs assistance. The formulation and recommendations should avoid the use of psychiatric jargon. Clear practical recommendations to improve coping, address behavioral problems, treat primary psychiatric disorders, and maintain safety are most helpful. Sharing an understanding of motivations that may underlie maladaptive behaviors can increase empathy for the child and family, but the consultant should also provide concrete, practical suggestions. One should assume that patients and parents will read the record, as can hospital staff and insurers.

Reasons for consultation: primary psychiatric illnesses

Depression

For a general review of depression please see Chapter 63.

Depression is common in the hospitalized child. It may be a secondary response to the stress of acute or chronic illness, or it may be primary presenting as psychosomatic illness or behavioral problems including self-harm. One barrier to the appropriate treatment of depression in hospitalized children is the misconception that depressed mood and symptoms are an appropriate response to serious illness. Another barrier to treatment is the difficulty of making the diagnosis of depression in a medically ill child given the overlap of somatic symptoms and depressive symptoms (Shemesh *et al.*, 2005). Individual and family therapy, play therapy, behavioral therapy, and medication are useful modalities in the hospital setting (see Chapters 62 and 63). Antidepressants are also being used medically in children and adolescents with preliminary studies reporting benefit (Kersun & Elia, 2007). Selective serotonergic reuptake inhibitors (SSRIs) are typically the first-line agent of choice as they are well tolerated, have limited interactions with other medications, and present a lower risk of intentional or accidental overdose (see Chapter 43).

Anxiety

Anxiety can be preexisting or secondary to the stresses of the medical condition and treatment. Children with preexisting generalized anxiety or specific fear of doctors, needles, and shots are likely to have more difficulty adjusting to medical assessment and treatment. In addition to the discomfort anxiety causes to children and parents, anxiety can interfere with procedures and complicate history taking and symptom assessment.

Age appropriate explanation of medical interventions for older children, and medical play with explanation for younger children, can decrease anxiety. Children from around 6 years of age can learn a variety of coping techniques to help them with anxiety provoking procedures. Many children will respond to distraction, breathing exercises, visualization, or hypnotherapy (Landier & Tse, 2010; Koller & Goldman, 2012).

Clinicians must pay attention to minimizing pain for every child (Greco & Berde, 2005). Effective interventions include preparation, relaxation, distraction, use of anesthetic creams before procedures, and treating chronic and acute pain with analgesics (Fein *et al.*, 2012; Sohn *et al.*, 2012). For young children, all painful procedures should occur in a treatment room and not in the child's bed nor in the playroom. Protecting the child's bed and the playroom as safe havens will eventually help the young child relax in these settings.

Despite quality pain management, relaxation techniques, and preparation for procedures, some children will continue to be too anxious to comply with treatment and may suffer sleep disturbance, nausea, or agitation during the hospital stay or in anticipation of visits to the hospital. Benzodiazepines may be helpful adjuncts to lessen debilitating anxiety. In young children, one must be aware of the potential for benzodiazepines to cause a "paradoxical reaction" with disinhibition and worsening anxiety.

Anorexia nervosa

For a general review of anorexia nervosa please see Chapter 71.

Pediatric hospitalization for anorexia usually occurs when there has been rapid or profound weight loss, cardiovascular abnormalities, electrolyte imbalance, or hypothermia. The goal of hospitalization is medical stabilization with nutritional assessment and treatment, psychological assessment of the child and family, and recommendation for level of psychiatric intervention after medical stabilization. Eating disorder protocols (also referred to as nutritional deficiency protocols) provide established guidelines for inpatient clinical care. The guidelines should include meal plans, weight expectations, and goals of the admission. The protocols are detailed and include restrictions of activity, observation during and after meal times and bathroom privileges only after weight gain has begun (Sylvester & Forman, 2008). Once the child is medically stable, recommendations about disposition can be initiated.

Psychosomatic illness

For a general review of psychosomatic illness please see Chapter 72.

Some children are admitted to pediatric units with intense, persistent somatic complaints such as headaches, abdominal pains, bowel complaints, neurologic symptoms, or fatigue. The pediatricians may suspect that the intensity of the symptoms or the combination of complaints exceeds what can be explained by a medical condition and reflects underlying emotional factors and may thus seek a psychiatric consultation. The pediatrician's assessment that psychological factors are influencing the somatic presentation is usually at odds with the child and parents' understanding of the etiology of the condition. Often the child and parents are viewed as overly invested in an exhaustive medical work-up to prove a purely medical etiology.

Commonly, psychiatric consultation is resisted, because it is viewed as evidence that the medical team either does not believe the symptoms or medical condition to be "real" or is unwilling to fully investigate all the medical possibilities. It is common for the family to seek multiple medical opinions and often to choose the most aggressive specialists. Diagnostic tests may be repeated to satisfy parental demands for action or in an attempt to decrease persistent patient and parental anxiety about undetected serious illness. Parents may overvalue insignificant positive findings from the diagnostic work-ups to vindicate their belief that a yet undiscovered medical etiology exists.

Hospitalization may be an important opportunity for a coordinated care plan addressing psychological and medical issues together. Presenting the consultant's role as one of helping the child cope with chronic symptoms that are interfering with school, peer activities, or family life is less threatening than suggesting that the consultant has been sought because the symptom intensity reflects psychological issues. The child and family must be reassured that the presence of the child mental health consultant will not be associated with reduced access to the medical team, but is truly an adjunct to ongoing medical care. The pediatrician plays the important role of re-examining the child regularly, reassuring the patient and family that no worrying new findings exist and not acquiescing to unnecessary testing.

Nonadherence

Nonadherence with medical treatments is common ranging from estimates of 50% to as high as 88%. Physicians recognize that education and an alliance with parents and children can improve patient adherence rates. More recently care providers are employing text messaging and other behavioral interventions to improve patient adherence with clinic visits and medications (Dowshen *et al.*, 2012; Ting *et al.*, 2012). There are many factors contributing to nonadherence including the medication regimen, family systems, denial, psychiatric illness, and relationships with medical providers.

When consultation is sought for nonadherence, usually it is because of risk to the child's health, escalating conflict in the family, or frustration with inappropriate use of medical resources. The consultant's task is to understand why the child is nonadherent and to work with the team to modify aspects of treatments that trouble the child where possible, while working

to help the child and family adopt strategies that support clinically important treatments. Treatable psychiatric disorders need to be identified and addressed. Treatment promoting supports, including disease specific support groups, more frequent meetings with clinicians and psychoeducation groups can be helpful.

Reasons for consultation: emergency consultations

Suicide attempts

For a general review of suicide attempts please see Chapter 64.

The most common emergent consultations relate to the suicidal or self-abusive child. The consultant's first recommendations focus on the child's immediate safety and the child's risk for self harm in the medical unit setting. Once safety has been assured, the consultant can assess the precipitants for the acts of self-harm and recommend appropriate treatment in the hospital and disposition.

Delirium

Delirium is commonly encountered in medically ill children. Also known as acute confusional state, delirium is a syndrome characterized by (i) acute onset and waxing and waning course, (ii) cognitive impairment or confusion, and (iii) disturbance of arousal. Delirium can occur either in the setting of an underlying general medical illness or secondary to substances including medicines or toxins. The mnemonic "I WATCH DEATH" provides an overview of the conditions commonly associated with delirium (Table 45.2); infectious and toxic etiologies (including medications) are the most common in the pediatric population.

The underlying mechanisms of delirium remain poorly understood, but it is thought to represent derangements in multiple neurotransmitter systems, particularly dysregulation of acetylcholine and dopamine. In addition to confusion, symptoms of delirium commonly include hallucinations, delusions, disorganized behavior, disorientation, and disruptions in memory, mood, affect, and the sleep-wake cycle (Turkel *et al.*, 2006). The nature of the disturbance of arousal in delirium varies. Hyperactive delirium is associated with combativeness and agitation. Hypoactive delirium is a state of quiet confusion and is often overlooked as the symptoms do not interfere with delivery of care.

Definitive treatment for the delirious patient is identification and treatment of the underlying cause of the syndrome, while managing symptoms in order to ensure safety for patients and staff. Management incorporates environmental interventions, including reassurance, use of environmental cues, and frequent reorienting to place and familiar people. Pharmacologic interventions can ease distressing symptoms including psychosis and fear as well as decrease agitation. Dopamine blockade is the mainstay of pharmacologic management and for adult patients intravenous haloperidol is the traditional treatment of

Table 45.2 Conditions commonly associated with delirium.

Infectious	Encephalitis, meningitis, syphilis, pneumonia, UTI
Withdrawal	Alcohol, benzodiazepines, sedative-hypnotics
Acute metabolic	Acidosis, alkalosis, electrolyte disturbances, liver or kidney failure
Trauma	Heat stroke, burns, post-operative
CNS pathology	Abscess, hemorrhage, seizure, stroke, tumor, vasculitis, normal pressure hydrocephalus
Hypoxia	Anemia, carbon monoxide poisoning, hypotension, pulmonary embolus, lung or heart failure
Deficiencies	B12, niacin, thiamine
Endocrinopathies	Hyper- or hypoglycemia, hyper- or hypoadrenocorticism, hyper- or hypothyroidism
Acute vascular	Hypertensive encephalopathy or shock
Toxins or drugs	Medications, pesticides, solvents
Heavy metals	Lead, manganese, mercury

Source: I WATCH DEATH (from Stern, T.A. *et al.* (2010) *Massachusetts General Hospital Handbook of General Hospital Psychiatry*, 6th edn, Philadelphia, PA: Saunders.)

choice (Jacobi *et al.*, 2002). Atypical antipsychotics have become increasingly first-line agents for delirious patients who are able to take oral medications (Karnik *et al.*, 2007). Benzodiazepines and diphenhydramine can compound the core symptoms of confusion and disorientation and should usually be avoided in the delirious patient (with the notable exception of delirium that is due to withdrawal from alcohol or benzodiazepines).

The challenging family

Parental behavior may be the reason for an urgent referral to the mental health consultant or to the team social worker. Parents may be refusing essential medical treatment for the child, including threatening to remove an ill child from the hospital against medical advice, or acting bizarrely. The reason for the parental actions may remain unclear, or may be explained by beliefs at odds with standard medical practice, mistrust of the hospital staff, psychiatric illness in the parent, or extreme anxiety. Hostile parents may interfere with critical care by frightening the medical staff.

Often parents who are obstructing needed care for their child are doing so because they are themselves overwhelmed with helplessness and are trying to control what they consider as uncontrollable. By helping the parent to feel that he or she is an essential member of the decision-making process and thus has some control in productive ways, many parents will step out of a combative stance and into a more collaborative one. Specific legal interventions may be implemented when parents prevent a life sustaining treatment and will be determined by legal parameters of the place of practice.

Child abuse

Physical abuse, neglect, and sexual abuse may result in emergent consultation and are discussed elsewhere in this book

(see Chapters 29 and 30). In the consultation setting, it is appropriate to restate the importance of suspecting abuse. Without educated suspicion, abuse will often go undetected. Suspicious injuries, implausible or inconsistent stories from caretakers, and inappropriate delay in bringing a child for medical care should raise suspicion, as should caretakers who ascribe the injury to siblings or self-inflicted injuries.

Suspicion of abuse must be reported to the appropriate social agency. When abuse is suspected, the child should be fully examined for other physical signs. It is important to notify authorities of other children known to be in a potential unsafe home. The pediatric unit may serve as a safe haven for a child while allegations are being investigated.

The pediatric unit may also be the setting in which the fabrication of medical illness by a parent or caregiver, widely known as Munchausen Syndrome by Proxy (MSBP), is either identified or investigated. As originally described, symptoms are inflicted on the child (e.g., contamination of a central line to induce bacteremia, asphyxiation to induce cardiac arrest); in variations of MSBP symptoms are exaggerated or elaborated and result in unnecessary medical interventions (hence the increasing use of the broader terminology Pediatric Condition Falsification and/or Medical Child Abuse). In a recent review, Squires and Squires (2010) discuss the “facilitating medical environment,” because of the nature of the abuse in MSBP, medical care providers and the health care system are often unintentional perpetrators of the abuse. The pediatric medical unit may be the primary setting as families or patients seek excessive medical treatment for their reported symptoms/illness. The psychiatric consultant may initially become involved as the medical team grapples with providing appropriate medical treatment when the history and presentation are inconsistent. When the child suffers harm related to these interventions, regardless of caregiver intent, medical child abuse has occurred.

Reasons for consultation: psychological distress in the medically ill children

Children with medical illnesses serious enough to warrant hospitalization are recognized as at increased risk for emotional disorders, with estimates of psychological distress in hospitalized children and adolescents varying from 20% to greater than 35% (Stoppelbein *et al.*, 2005). Those conditions that result in long-term physical disabilities or impact on the CNS pose additional risk (Meyer *et al.*, 2004; Poggi *et al.*, 2005), as may certain symptoms and challenges associated with specific diseases. Official practice parameters released by the American Academy of Child and Adolescent Psychiatry in 2009 offer principles for the assessment, management, and treatment of the medically ill child (DeMaso *et al.*, 2009).

Coping with chronic illness

Chronically ill children should not be defined by their illnesses, that is, there is no typical child with diabetes or classic child with

asthma. To the contrary, chronically ill children have the same range of personalities, and coping styles observed in healthy children and are engaged in mastering the developmental milestones and challenges they share with their peers.

Estimates of psychological morbidity associated with chronic illnesses in childhood range from 10% to 30%, which is only slightly higher than the general pediatric population (Barlow & Ellard, 2006). Greater morbidity is associated with multiple hospitalization admissions (Geist, 1977). Other documented risk factors for adaptation to chronic illness include physical disability and brain dysfunction, pain frequency, younger age, poverty, single parent family, and increased psychological symptoms in the parents (Knapp & Harris, 1998). Parental anxiety, anger, sadness, guilt, or blame can impede adjustment (Wagner *et al.*, 2003; Vance & Eiser, 2004).

Specific illnesses present specific challenges, (some are discussed below). That said, innumerable unique factors influence how problematic any given challenge is for an individual child. It is the consultant's job to understand the unique meaning of the illness to the child and family and to assist in the process of adaptation. The consultant will need to ask many questions to elucidate the child's subjective experience of the illness, such as what is the hardest aspect of the illness or treatment from the child's perspective, how does it affect the child's image of himself, and are there specific worries about the future? Inquiries about the impact on peer interactions or favorite activities, areas of conflict between the child and parent in relation to the illness, and the child's perception of the parents' worries may be useful.

Asthma

Asthma is the most common chronic illness of childhood with a pediatric population prevalence of 5–10% and an increasing mortality rate from 1980 to 1998 that appears to have reached a plateau (Akinbami & Schoendorf, 2002). Racial and ethnic disparities account for much of the increase in morbidity (McDaniel *et al.*, 2006). Recent studies have sought to understand the factors that affect adherence, delineate common psychosocial stresses that may act as triggers for asthma attacks, and devise psycho educational programs, combined medical and psychological treatment strategies, and teach stress management skills to improve adherence and decrease morbidity (Self *et al.*, 2005; Peters & Fritz, 2010).

Hospitalization is an opportunity to emphasize education. Clear guidelines on when to call the pediatrician can be established while seeking input from the family about barriers to these contacts. Triggers in the home can be addressed realistically and empathically in light of the exacerbation that led to admission. Common triggers, such as smoking and pets, require a major commitment from family members in order to enact change. School-related issues need to be explored from the perspective of the child (e.g., embarrassment associated with going to the school nurse) and the school (e.g., access to inhalers in the classroom). Strategies to improve parent and child anxiety and to address parent child conflicts around adherence are valuable.

Diabetes

Insulin-dependent diabetes presents special medical challenges associated with control of blood sugars and insulin delivery, as well as special emotional challenges related to the primary role of food as a source of nurturance and soothing. The acute consequences of blood sugar abnormalities include symptomatic hypoglycemia, hyperglycemia, and ketoacidosis and may lead to hospitalization. The long-term sequelae include effects on vision, renal function, and neuropathy. Symptoms associated with hypoglycemia are often difficult for parents to differentiate from common irritability in young children or for older children to recognize as different from anxiety in themselves. This leads to either more frequent blood testing or a tendency to keep the blood sugars at a higher level than the physician would recommend. Some children will have considerable anxiety about hypoglycemia, either in response to an actual episode or arising independently. It is a key to treat anxiety disorders in order to improve adherence as well as recognize emerging eating disorders in the female teenage population as a factor in nonadherence (Jacobson, 1996; Hamilton & Daneman, 2002).

Nonadherence in insulin dependent diabetes can be life threatening. Blood testing (hemoglobin A1C) enables pediatricians to assess the child's adherence over an extended period and may be considered an appropriate factor for protocol driven mental health consultation. Subcutaneous insulin pumps can now deliver a continuous infusion of rapid-acting insulin at both basal and bolus rates, allowing for tighter control of blood sugars when combined with careful tracking of carbohydrate intake. Compared to long-acting insulin regimens, additional benefits that may be especially appealing to adolescents include greater flexibility in meal and activity planning and more discreet delivery of insulin.

Cancer

Childhood cancer presents numerous challenges to adaptation and development, fortunately though most studies suggest that childhood cancer survivors adapt well following treatment (Zeltzer *et al.*, 2009). There are predictable high stress points in the course of an illness that often coincide with hospitalization including diagnosis, onset of treatment, and treatment completion as well as, for some, the time of a recurrence, renewed treatment, and end of life care. Psychological support for the child and parents is particularly beneficial at these critical points. Siblings also benefit from support at the various transitions during the course of the illness (Alderfer *et al.*, 2010).

Diagnosis of a life threatening illness is understandably frightening to parents and older children creating a family crisis. Some children and parents may respond to diagnosis and aspects of treatment by exhibiting symptoms observed in posttraumatic stress syndrome (Stuber *et al.*, 1998; Norberg and Boman, 2008; Phipps *et al.*, 2009). Psychosocial assessment to screen for distress in families of a child with a new diagnosis of cancer can help identify families most at risk (Kazak *et al.*, 2012).

Frequently children and families will face the child's cancer diagnosis with past experiences with cancer in a family member, or close friend, coloring their understanding of what lies ahead for their child. It is helpful to invite the child to share his understanding of the diagnosis as an opportunity to differentiate the child's situation from that of others, while potentially uncovering misconceptions about the illness.

Challenges to psychological adaptation include persistent pain (whether as a result of the cancer or the procedures), persistent debilitating side effects of treatment such as nausea, alteration in body image, school disruptions, compromised peer relationships, interference with ability to engage in favorite activities, or conflicts in the family (Hockenberry *et al.*, 2011; Kurtz & Abrams, 2011). Adolescents may worry about future health status, sexual function and reproductive capacities, and future career choices (Patenaude & Kupst, 2005). This age group benefits from special attention to their specific developmental needs (Abrams *et al.*, 2007).

During the course of cancer treatment, many children develop strong positive relationships with members of the medical team, experience a special closeness with supportive parents, and maintain key preexisting peer friendships while acquiring new friends in the hospital. Many children will report feeling a special sense of purpose for living as a result of the cancer diagnosis and most will be treated with special status as a result of the illness. Resilience and positive life change are also part of the cancer experience (Phipps *et al.*, 2012).

Organ transplantation

Liver, kidney, heart, and lung transplantation are well-established practices in the pediatric population and intestinal transplantation is beginning to be undertaken. Transplantation centers in the United States are required to include psychological assessment in order to receive accreditation. Data on criteria for approval of candidacy for transplant are vague. The serious disease process leading up to transplantation, the risks of surgery, the long-term medical management of organ rejection posttransplantation, the threat to survival, and the vast array of medical treaters involved place these children in the highest of high risk populations. It is noteworthy therefore that the data on adjustment to liver and renal transplantation suggests that overall these children view themselves as healthy and competent (Tong *et al.*, 2011). Not surprisingly, some children and parents are vulnerable to anxiety and experience distress posttransplant. It is therefore important that transplant centers involve mental health consultants and provide emotional support (Shemesh, 2008).

Inflammatory bowel disease

Inflammatory bowel disease (IBD), including Crohn's disease and ulcerative colitis, are distinct disease processes characterized by chronic inflammation of the gastrointestinal tract with relapsing and remitting courses that lead to chronic abdominal pain, bloody diarrhea, and fatigue. Neither Crohn's disease nor

ulcerative colitis has a cure, and they are managed through medical and surgical interventions aimed at controlling inflammation. Pain, unpredictability, and functional impairment are only some of the potential challenges posed to the psychosocial development of the child with IBD. Treatment with systemic steroids is a mainstay of IBD regimens during acute flares and may lead to derangements in cognitive function, mood, and behavior, sometimes including severe symptoms such as major depression or psychosis. Additional stressors include adaptation to the physical sequelae of IBD (e.g., short stature, weight loss, weakness, and delayed puberty) as well as physical sequelae of treatment (e.g., steroid-induced acne, visible feeding tubes, and J-pouches) and embarrassment around needing frequent use of public bathrooms—including in the school setting.

Rates of depression among adolescents with IBD vary widely between studies, but have been found to be as high as 25% (Szigethy *et al.*, 2004). Moreover, children with IBD have been found to have increased rates of anxiety as well as decreased psychosocial health, social functioning, and school functioning compared to well-peers (Mackner *et al.*, 2006; Greenley *et al.*, 2010). The mental health consultant is often involved in the care of IBD patients in both inpatient and outpatient settings. Psychosocial interventions (including psychoeducation, school-based services, and support groups), talk therapy (including cognitive behavioral therapy (CBT) and narrative therapy), and psychopharmacology aimed at depression, anxiety and insomnia all have demonstrated efficacy in adults or children with IBD (for review, see Szigethy *et al.*, 2011).

Cystic fibrosis

Cystic fibrosis (CF) is the most common life-limiting genetic disorder among Caucasian populations, affecting 1 in 2500 newborns, or more than 30,000 individuals in the United States and 7000 in the United Kingdom (Davies *et al.*, 2007). CF is a commonly encountered diagnosis in the inpatient pediatric medical setting. Typically diagnosed in infancy or early childhood, CF is caused by a gene defect in the chloride transport protein that leads to complex, multisystem disease, most notably chronic pulmonary inflammation and infection as well as gastrointestinal sequelae including pancreatic insufficiency with malabsorption and failure to thrive. Treatment advances have enabled many children with CF to live well into adulthood, but it remains a chronic and progressive life-limiting illness. Treatment regimens aimed at maintenance of pulmonary and systemic health are very demanding, and typically require strict dietary regimens, multiple medications, vigorous daily physical therapies, and both chronic and acute antibiotics. For many children, periodic exacerbations of pulmonary disease require repeated hospitalizations for “clean-outs,” consisting of weeks-long admissions for parenteral antibiotics and aggressive physical therapy.

Despite the staggering demands of the diagnosis on child and family, most children and families living with CF report high quality of life and have rates of psychopathology similar to cohorts of well peers (Szyndler *et al.*, 2005). Nevertheless

a full range of psychiatric problems have been reported in children with CF, and some studies have shown higher rates of psychopathology among children with CF, including anxiety, depression, and eating disorders emerging in adolescence (Quittner *et al.*, 2008; Smith *et al.*, 2010). As with other chronic illnesses, nonadherence is a significant issue for adolescents with CF and needs to be monitored closely.

Neurologic illness

Epilepsy is the most common neurologic disorder of childhood, affecting between 0.5% and 1% of children under age 16 (Shinnar & Pellock, 2002). Epidemiologic investigations around the globe and in both community and hospital-based settings have consistently demonstrated that psychiatric comorbidity is over-represented in pediatric epilepsy, with rates ranging from 33% to 77% (Davies *et al.*, 2003; Plioplys *et al.*, 2007).

Epilepsy is commonly associated with attention deficit hyperactivity disorder (ADHD), depression, anxiety disorders, and autism spectrum disorders (Jones *et al.*, 2008). Rarely, interictal psychotic disorders may occur, or psychosis may be a feature of partial-complex seizure semiology. Some antiepileptic drugs may cause poor concentration, inattention, impulsivity, and/or hyperactivity; others have been associated with depressed mood or mood lability. For children with epilepsy who require pharmacologic management—ideally in combination with cognitive behavioral or other therapy—SSRIs remain first-line for depression and anxiety. Careful attention should be paid to potential interactions with hepatically metabolized anti-epileptic drugs and cytochrome P450 inhibitors, including fluoxetine, paroxetine, and fluvoxamine. For children with comorbid ADHD, there is mounting evidence that methylphenidate treatment is safe in children with epilepsy and clinical guidelines state that benefits outweigh risks (Davis *et al.*, 2010; Koneski *et al.*, 2011).

Encopresis and soiling/wetting

Soiling may be voluntary or involuntary, but is most frequently encountered as encopresis, which is involuntary and paradoxically related to constipation (“overflow incontinence”). Chronic withholding of stool leads to colonic distension and impaction, followed by eventual disruption of normal signals to defecate and leakage around hard impacted stools. Encopresis is generally managed by the pediatrician with a combination of laxatives and behavioral interventions aimed at re-establishing normal bowel habits, including short periods (<5 min) of toilet sitting after meals (to capitalize on the gastrocolic reflex), self-initiated toileting and self-management of cleanliness.

Primary nocturnal enuresis (bedwetting in a child who has never been dry) is extremely common, but can be a significant social stressor and when prolonged is associated with poor self-esteem. Secondary nocturnal enuresis (bedwetting in a child who has been dry for 6 months or more) is sometimes precipitated by psychological stressors. Daytime wetting is more commonly associated with psychological disturbance than nocturnal wetting. These conditions are generally managed

by the pediatrician after history and physical examination has ruled-out medical causes, with a nonpunitive approach and options including behavioral interventions (limiting evening liquids, voiding at daytime intervals and/or before bedtime) and sometimes medications (desmopressin acetate, anticholinergic agents, and imipramine) that provide symptomatic control. Bedwetting alarms are the only demonstrated effective strategy for curing nocturnal enuresis, with reported success rates as high as 66–70% (Graham & Levy, 2009).

Children affected by encopresis and enuresis are generally emotionally healthy, but soiling and wetting can be exacerbated in children with anxiety or ADHD, and successful treatment sometimes requires treatment of comorbid psychiatric illness. For these children, assessment of adherence and psychopharmacology aimed at inattention or anxiety can be an essential part of successful treatment and maintenance of remission. Mental health professionals may also be involved for refractory cases of soiling, when constipation is not playing a part or the problem involves voluntary deposition of feces in inappropriate places. Such a pattern is often accompanied by other emotional or behavioral problems.

Dying in the hospital

The death of a child is an enormous tragedy affecting every member of the child's family. There is no way to protect a child or family from the unique pain of the loss of a child, but sensitive care may serve to lessen regrets and support bereavement (Kreicbergs *et al.*, 2004). Attending to pain, anxiety, and privacy/dignity needs is key. Adapting the medical setting to allow parents to nurture the dying child or facilitating a child's return home to die can play a significant role in the family's experience of the death and the subsequent bereavement (Stevenson *et al.*, 2013).

The emotional impact on the medical team deserves careful attention in order to preserve the team's ability to deliver quality care into the future. The grieving process of the staff warrants recognition. Some units will have staff meetings including the child mental health consultant or other facilitator after every death or after those deaths that are most troubling to staff members (Bateman *et al.*, 2012).

Many of the hospital-based pediatric deaths occur in neonatal intensive care units or during infancy. Key to supporting the family of a dying infant is respecting the infant's full status as a loved child. This may include facilitating religious ceremonies such as a naming or christening, creating mementos such as photographs, footprints, or a lock of hair, and creating the most loving situation possible for the moment of dying such as providing a private room and allowing a parent to hold the infant at the time life support is disconnected.

From age 3 years onwards, the child's personal experience of impending death should be considered. The child should be offered developmentally appropriate opportunities to express thoughts and fears associated with dying either with words, drawings, or through play. It is common for even 3 and 4 year

olds to verbalize explicit thoughts of joining dead grandparents and seeing angels, but it is also common for dying children to focus only on wanting parents with them at all times, and exhibiting a shift in behavior with more resistance to medical treatment, loss of interest in activities and food, but without any explicit verbalization of an awareness of dying.

Children of all ages, but especially younger children, are likely to take their cues about whether explicit discussion of death is permissible from parents and caregivers. When parents invite this dialog, it is more likely to occur. When parents signal that such discussion would be unbearable, the child is likely either not to speak about dying or to talk with a medical staff member when the parent is not present.

Child mental health consultants may help ready parents for discussions with their dying child. Asking open ended questions about worries, inquiring whether the child has questions that he is afraid to say aloud, or asking if he thinks about peers from the hospital who have died may serve as invitations to begin the dialog. Reminding children that articulating worries does not make them happen may free some children who are worrying silently to speak. Many parents will feel more comfortable embarking on end of life conversations with a child if they are told that they can welcome the child's questions warmly without having specific answers. "I am interested in your ideas." "What got you wondering about that?" "Your good questions deserve good answers. I want to think about that or talk to our minister or the doctor." These are examples of reasonable responses to a child's existential or medical questions. In the role of child mental health consultant, one of the most useful comments in response to questions about death is to tell a child "I don't know what it is like to be dead, because I have never been dead. But, I am always interested to hear children's ideas about it."

Children from age 7 onward may talk about the life experiences that they will not get to enjoy. These discussions challenge a parent's or professional's ability to bear the sadness of facing an untimely death as well as whether to talk directly with a child about their death (Kreicbergs *et al.*, 2004). The child may talk about not getting to attend the fifth grade, never being able to drive a car, or not growing up to be a doctor or a teacher. It is often the specificity of the opportunities lost in the words of a child that is so evocative. There is a sense of privilege that one experiences in listening to children as they face the end of their lives that is as special as it is sad.

Often children will talk about being tired of the fight against the disease and will look to parents for permission to stop treatment. When the surviving family members can support each other in the painful process of letting go of the beloved child, believing that everything that could be done was done, and that further treatment would be unfair to the child, the final phase of dying can seem more peaceful. In the setting of a long battle against an illness, it can be easier to get to this difficult emotional state. In the setting of an acute event with little time for adjustment, or when parental discord interferes with the parents' ability to grieve together, such peace is harder to achieve.

The consultant should encourage hospital staff to follow up with parents 6 months to a year after the death of a child. Parents are appreciative when staff attend memorial services and funerals, write sympathy cards, and make telephone calls (Bedell *et al.*, 2001; MacDonald *et al.*, 2005). Telephone calls provide an opportunity to assess the parents grieving and need for referral as well as help the staff member connect with the family.

Conclusion

Child mental health consultants must stay attuned to the changes in the field of pediatrics. Advances in pharmacology, genomics, and technology offer new hope and new challenges to psychosocial adaptation. Patterns of access to consultation will need to reflect shorter hospital stays and utilization of outpatient venues. New technology, such as telemedicine, may offer novel access to consultative expertise. Research in adherence outcomes, efficacy and quality of life become increasingly important as the financial pressures of modern medicine force the consultant to justify the value of the work.

However, many of the key features of quality consultation will remain unchanged. The consultant will continue to bring to the multidisciplinary medical team the combined expertise of psychodynamic understanding, psychopharmacology, developmental perspective on the meaning of illness, adaptation to trauma, knowledge of psychiatric conditions, behavioral interventions, and CNS influences in medical illness and as a result of medical treatment. The goal will remain to answer the consultation request in a thoughtful, timely fashion that respects the needs of the child, the family and the treatment team while facilitating quality of care and quality of life.

Mental health and resilience in children and adolescents affected by HIV/AIDS

Theresa S. Betancourt¹, David J. Grelotti^{2,3} and Nathan B. Hansen⁴

¹Department of Global Health and Population, Harvard T.H. Chan School of Public Health, Harvard University, Boston, MA, USA

The global impact of HIV/AIDS on children and adolescents

Despite significant advances in prevention and treatment, HIV/AIDS (human immunodeficiency virus/acquired immune deficiency syndrome) continues to exact a hefty toll on the world's children. An estimated 330,000 children under 15 were newly infected with HIV in 2011 (over 90% in sub-Saharan Africa), and 40% of new HIV infections are among adolescents and young adults aged 15 to 24 (UNAIDS, 2012). An estimated 3.4 million children and 5 million adolescents and young adults are living with HIV infection (UNAIDS, 2012; UNICEF, 2012).

In addition to those directly infected, the global HIV/AIDS pandemic has also created considerable strain on families and communities. An estimated 17.1 million children have lost one or both parents to HIV/AIDS (UNICEF, 2012), 88% of whom live in sub-Saharan Africa. In addition, many children live with HIV-infected parents and caregivers. Collectively referred to as orphans and children made vulnerable by HIV/AIDS (OVC), many HIV-affected youth lack: access to health care and educational resources, basic safety and economic security, and attachment figures (Betancourt *et al.*, 2010a).

With the advent of antiretroviral therapy (ART), and increasing global access, HIV is slowly becoming a chronic disease. However, there is a considerable treatment gap in many resource-poor areas, with only 28% of treatment eligible children (compared to 58% of adults) receiving appropriate therapy (UNAIDS, 2012). Without treatment, HIV/AIDS has significant consequences for health and mortality in children. But even with treatment, HIV can impact development and health, including

mental health, and is associated with a number of adverse outcomes for children (Benton, 2011; Rydström *et al.*, 2013).

To date, global health funding to address HIV/AIDS has been largely spent on the delivery of ART, but there is increasing recognition of the importance of mental health (Freeman *et al.*, 2005). However, despite the interrelationship between HIV and mental health, and the impact of mental health on engagement and retention in, and adherence to HIV treatment, the extent to which mental health treatment is delivered as a routine part of HIV care is not clear. In the United States, HIV-infected children and adolescents may be more likely to receive mental health care than HIV-affected youth as a result of receiving their care through multidisciplinary clinics (Mellins *et al.*, 2012). Access to mental health services is far more limited in low- and middle-income countries (LMIC) (Betancourt *et al.*, 2012).

The effects of HIV/AIDS on the social ecology, child development, and mental health

An ecological and biopsychosocial lens illuminates how mental health and well-being are shaped by the interplay between individual, family, community, and societal factors (Masten, 2001; Sapienza & Masten, 2011). Bronfenbrenner stressed how “settings” of development interact to support positive child development, creating a nurturing physical and emotional environment that includes, and extends beyond, the immediate family to peer, school and community settings, and cultural and political belief systems (Bronfenbrenner, 1979).

For children, HIV represents a fundamental alteration of the social ecology which undergirds healthy child development,

disrupting factors across all levels (Werner, 1989; Benard, 1995; Cowan *et al.*, 1996; Betancourt *et al.*, 2014). For example, children living with an HIV-positive parent may experience worry, anticipatory loss and uncertainty about the future. Young people also have to cope with secrecy and stigma against families affected by HIV/AIDS (Lin *et al.*, 2010). In addition, children affected by HIV often assume adult roles prematurely. In fact, AIDS-orphans have a nearly twofold risk of HIV infection (Stein *et al.*, 1999; Zhang *et al.*, 2009) and often face financial hardships (Cluver *et al.*, 2009a) and relocation from important social networks (Zhao *et al.*, 2011a).

Resilience is the attainment of competence as well as desirable social and emotional adjustment, despite risks (Rutter, 1985; Luthar, 1993). This definition acknowledges the developmental threats facing children affected by HIV/AIDS, and highlights the physical, social, and individual outcomes relevant to healthy development (Rutter, 2006). As protective processes and factors mitigating the impact of risks have not been well explored, it is important to understand the full range of processes with potential to increase resilient outcomes in HIV/AIDS-affected children and to use this knowledge to develop interventions that may be implemented across different levels of the social ecology (Figure 46.1).

The relationship between HIV and mental health is often described as bidirectional, meaning that the effects of living with HIV/AIDS or having an affected family member can increase risk for mental illnesses such as anxiety and depression. Moreover, poor mental health can lead to behaviors which place individuals at risk for HIV infection (Briere & Jordan, 2004; Cluver *et al.*, 2007, 2012). In families, psychological sequelae related to HIV/AIDS have been associated with parental hopelessness, depression, and risk behaviors such as drug abuse and sexual risk taking (Rochat *et al.*, 2006).

HIV/AIDS amplifies vulnerability to community-level risk factors. HIV/AIDS-related stigma can pose barriers to accessing social supports that typically support families and children in challenging circumstances (Cluver & Orkin, 2009). Lack of community understanding can compromise perceived social equity, work opportunities, and inclusion in religious organizations (Anderson *et al.*, 2008; Rutta *et al.*, 2008). Loss of employment combined with taxing medical expenses can compound other risk factors and drive families into poverty (Silver *et al.*, 2003). Although access to HIV-related health care, including ART, is improving (Perez *et al.*, 2004; Betancourt *et al.*, 2010b), systems of social welfare and protection that support the socio-emotional needs of children made vulnerable

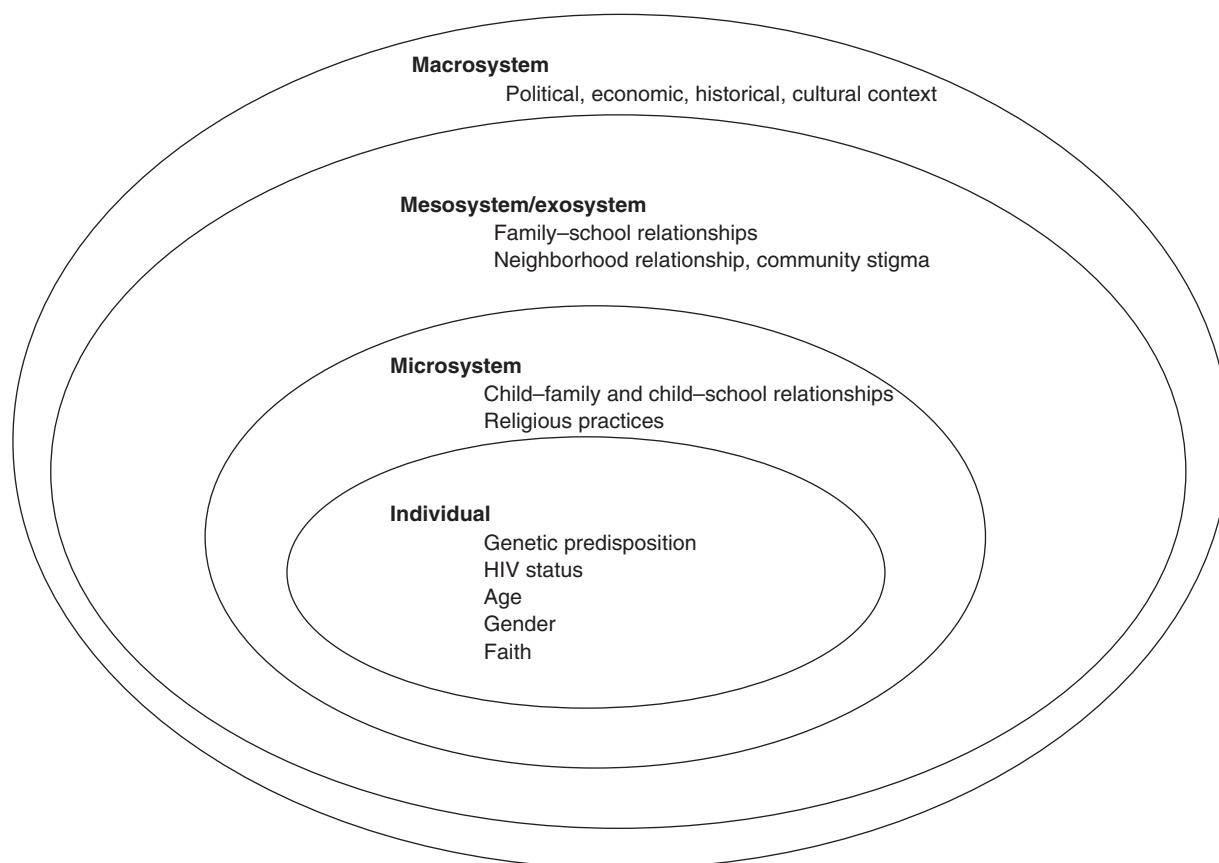

Figure 46.1 The social ecological model of risk and protection for children affected by HIV/AIDS. *Source:* Reprinted with permission from Sage Publications.

by HIV/AIDS remain weak or nonexistent in many low resource settings (UNAIDS, UNICEF, USAID, 2004; UNICEF, 2006).

Brief overview of HIV and child health

As our treatments and interventions are linked to our understanding of HIV virology, readers may benefit from a brief review. HIV is the virus that causes AIDS. The virus invades and infects cells of the body that mediate immunity, most notably CD4+ T-lymphocytes (CD4 cells). HIV replicates within infected cells, or may lie dormant, evading the body's immune system as well as currently available drug treatments.

The amount of CD4 cells in blood samples serves as a proxy for immune status. The absolute number of CD4 cells per cubic millimeter of blood, or CD4 count, is used for children older than 5 years and adults. As CD4 count is not as meaningful clinically in younger children, CD4 percentage is used to assess immune status in children younger than 5 years. A patient's CD4 count and CD4 percentage is related to susceptibility to certain opportunistic infections. AIDS is defined by the presence of an opportunistic infection or the amount of impaired immunity as measured by absolute CD4 count percentage below a certain cutoff.

Currently, there is no cure for HIV. However, antiretroviral therapy (ART) can effectively manage the disease. These drugs are divided into classes based on how they interfere with HIV replication. Single classes of drugs used independently have not proven effective in combating HIV. The use of at least three drugs from two or more drug classes in combination, however, is highly effective. Early initiation of ART is associated with reduced drug resistance, preserved immune functioning, and delayed disease progression. To maintain viral suppression and prevent drug resistance, however, consistent adherence is necessary. It is important to note that, while treatment safety is constantly improving, antiretroviral drugs are highly potent and can have toxicity or unpleasant side-effects (Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2013). Moreover, the developmental consequences of long-term use of these drugs in children are largely unclear.

Routine HIV testing is recommended for all persons aged 13–64 by the Centers for Disease Control and Prevention (CDC) in areas where HIV prevalence exceeds 0.1% or where the prevalence is unknown. The CDC further recommends annual testing and for all individuals at risk for HIV, even in areas of low HIV prevalence (Branson *et al.*, 2006). The American Academy of Pediatrics has adopted similar guidelines and recommends that pediatricians offer HIV testing at least once by age 16–18 years (Committee on Pediatric AIDS, 2011).

In nations with robust health systems, anyone testing positive for HIV infection will be offered ART and be expected to stay on treatment for life. Evidence continues to accumulate that early treatment is related to improved health outcomes in HIV. Unfortunately, in many LMICs, children are often only eligible for ART if they develop an HIV-related illness or a low CD4

count. However, because of the importance of ART in preventing morbidity and mortality related to HIV encephalopathy, the WHO recommends initiating ART for life in all children under the age of 2 years (World Health Organization, 2010).

HIV is associated with a host of medical conditions. In general, untreated and severely immunocompromised children experience considerable morbidity and mortality as a result of opportunistic infections. With treatment, clinicians have observed decreasing progression to AIDS, hospital admissions and deaths among these children (Judd *et al.*, 2007). However, even treated HIV-infected children suffer sometimes subtle metabolic, cardiovascular, renal, bone, and central nervous system problems as a result of HIV infection, medication side effects, or viral-mediated inflammation (Hazra *et al.*, 2010).

Although a lengthy description of medical comorbidities of the HIV-infected child and adolescent is beyond the scope of this chapter, symptoms of medical illness might be confused for or coexist with psychosomatic complaints. Psychosomatic problems are present in 28% of treated, clinically and immunologically stable HIV-infected children (Nozyce *et al.*, 2006). Psychosomatic complaints have been associated with a variety of factors: medical diagnoses and hospitalizations, perception of parent rejection, stressful life events, conflict, parental distress, school adjustment, younger age, female sex, ethnicity, and drugs and alcohol (Bursch *et al.*, 2008). Clinicians should be aware that somatic symptoms may reflect occult illness related to HIV, so close coordination with medical colleagues is of utmost importance.

Transition from pediatric to adult care has also been an important subject in working with HIV-infected children and adolescents. Many pediatric centers have developed formal approaches to the transition process. Important elements include transition teams, attention to developmental factors, patient education, and skill building. HIV-infected children with depression and/or substance abuse are perceived to have a more difficult transition (Gilliam *et al.*, 2011).

Modes of HIV transmission in children and adolescents

Different modes of HIV transmission are relevant for different age groups. Young children with HIV are often infected perinatally or “vertically” from mother to child. If the mother is infected with HIV, there is an increased risk of transmission to the child at or around the time of birth. Infection may occur during pregnancy, but this is less likely. Fortunately, prevention of mother-to-child transmission (PMTCT) of HIV has been possible through the use of HIV testing and the provision of antiretroviral drugs. Antiretroviral medications provided to HIV-infected mothers also prevent HIV transmission to an uninfected child through breastfeeding, which is critical for areas where formula-feeding is not possible due to lack of safe drinking water.

Sexual contact, especially unprotected sexual intercourse, is a common vector for transmission of HIV. Forty-two percent of HIV-infected youth continue to engage in unprotected sexual intercourse despite knowledge of their HIV status (Tanney *et al.*, 2010), and 65% of sexually active perinatally infected adolescents report unprotected sex (Mellins *et al.*, 2011). Other problematic sexual risk factors include multiple concurrent partners, number of unprotected sexual acts, and unprotected sex with serodiscordant persons. Intravenous drug use, especially sharing needles, is also a common mode of transmission.

HIV and its neurological impact in children and adolescents

HIV is a neurotropic virus which directly and indirectly damages the brain (Dunfee *et al.*, 2006; McArthur & Smith, 2013). HIV crosses the blood–brain barrier, where infection of brain cells leads to the release of cytokines and other agents which have a toxic effect on the brain (Davis *et al.*, 1992; González-Scarano & Martín-García, 2005; Kaul *et al.*, 2006). Chronic, low-grade inflammation as a result of HIV may also have a lasting effect on the brain and cognition (Chang *et al.*, 2011; Garvey *et al.*, 2012).

Unlike in adults, children can experience neurologic disease before clinically significant immunodeficiency (Van Rie *et al.*, 2007). A common neurological sequela of HIV infection in children is HIV encephalopathy. HIV encephalopathy is characterized by acquired microcephaly, developmental delay and/or regression, and motor deficits. Before widespread use of ART, HIV encephalopathy was relatively common, with its greatest incidence before 2 years of age. Antiretroviral treatment has been responsible for prevention of HIV encephalopathy, and treatment of a child with HIV encephalopathy can prevent progression of the illness or death (Patel *et al.*, 2009). However, even with treatment there are a large number of residual symptoms.

Evidence of in utero infection, lack of maternal ART use, and initiation of ART in children after 12 weeks of age are also associated with neurodevelopmental delay. Evidence from resource-poor settings appears to mirror findings from resource-rich areas. Neurodevelopmental deficits using a wide range of assessment tools were reported in 6–40% of HIV-infected children who have never received antiretroviral treatment (Le Doaré *et al.*, 2012).

HIV-exposed but uninfected children from resource-rich settings have no apparent global developmental delay as infants, but subtle deficits in cognitive, motor, language, and behavior may be found in preschool-aged children (Le Doaré *et al.*, 2012). In resource-poor settings such as Africa, HIV-exposed but uninfected children have been shown to have greater cognitive, motor, and expressive language impairment than children with no exposure to HIV (Le Doaré *et al.*, 2012).

In many countries, many HIV-affected children are less likely to be enrolled in or attend school (Monasch & Boerma,

2004; Evans & Miguel, 2007; Mishra *et al.*, 2007), or to be in an appropriate grade for age (Bicego *et al.*, 2003; Zhao *et al.*, 2011b). In China, children affected by HIV had poorer school performance and more behavioral problems when compared to unaffected peers (Tu *et al.*, 2009). Some orphaned children may be less likely to finish school. Children who lost their mothers, double orphans, those living in higher poverty, and girls may be more vulnerable (Guo *et al.*, 2012).

HIV and psychopathology

Multiple studies indicate that children living with and affected by HIV are at risk for a wide range of psychiatric disorders. Among clinically and immunologically stable children aged 2–17 years, behavioral problems, learning problems, attention deficit hyperactivity disorder (ADHD) anxiety, and conduct problems have been reported (Nozyce *et al.*, 2006). Perinatally infected children with HIV and their noninfected, HIV-exposed peers living with an HIV-infected parent also demonstrate high rates of mental health problems (27–69% and 26–70%, respectively) (Williams *et al.*, 2010; Gadow *et al.*, 2010, 2012; Mellins *et al.*, 2012).

Reasons for the high rates of mental disorders in HIV-infected youth and HIV-exposed but uninfected children are not well understood, but a number of potential risk factors are speculated, including genetic factors (many of which may put youth or their parents at risk for HIV infection), HIV disease severity and HIV-related neurocognitive factors, caregiver HIV disease and AIDS-related death, and caregiver psychiatric disorder and/or substance use and other social and environmental factors such as stigma (Bauman & Germann, 2007; Cluver *et al.*, 2008; Doku, 2009; Andrinopoulos *et al.*, 2011; Gadow *et al.*, 2012). Moreover, it must be noted that youth are at increased risk of becoming infected with HIV as a result of mental disorders. In children with HIV infection as a result of engaging in high-risk behaviors, substance abuse is common (Tanney *et al.*, 2010; Mellins *et al.*, 2011). Depressive and anxious symptoms are more common in adolescents engaging in sexual risk behavior (Lehrer *et al.*, 2006). Young men who have sex with men who engage in unprotected anal intercourse and are thus at greater risk of HIV, have higher levels of depression and psychological distress (Perdue *et al.*, 2003).

Although post-traumatic stress disorder (PTSD) is common among adults with HIV, it is unclear how common PTSD is in HIV-infected youth. Trauma-related symptoms are found in many HIV-infected children (Ingerski *et al.*, 2010), and 23.3% of an urban sample of 18–24 year-olds with HIV had PTSD (93% reported the HIV diagnosis as a traumatic event) (Radcliffe *et al.*, 2007). Childhood physical or sexual abuse, intimate partner violence, sexual assault, and other or multiple forms of victimization are all common in men (including young men who have sex with men), women, and transgendered women behaviorally-infected with HIV (Clum *et al.*, 2009; Reisner *et al.*, 2009a; Brennan *et al.*, 2012; Whetten *et al.*, 2012).

The convergence of risk factors, such as substance abuse and violence, working in concert to increase risk of HIV infection led to the idea of *syndemics*, or intersecting epidemics with “mutually enhancing” social, physical, and structural components that interact to increase the vulnerability of a population to a disease (Singer, 2010). It is likely that to be effective, prevention and treatment interventions will have to take into consideration syndemics and the complex biopsychosocial context of HIV.

Mental health and ART adherence

Adherence to ART for life is essential for the effectiveness of HIV treatment regimens, and some of the biggest barriers to adherence are mental health or behavioral problems. In research studies, adherence among study populations of adolescents ranges from 74.5 to 84.0% (Murphy *et al.*, 2005; Williams *et al.*, 2006; Rudy *et al.*, 2010). Children in school, raised by caregivers other than the biological parent, and enrolled in reminder programs and those with less substance use, higher life satisfaction, lower psychological distress, concrete rather than abstract reasoning skills, less sexual risk behavior, simplified drug regimens, and fewer side effects have higher adherence. Similarly, children who have dropped out of school and those with housing instability, fear of HIV stigma and discrimination, poor coping style, substance use, depressive and anxiety symptoms, childhood sexual abuse, prior suicide attempt(s), advanced HIV disease, more negative appraisal of their ability to remain adherent (self-efficacy), and more negative notions of what being adherent would do for them (outcome expectancy) have higher nonadherence. Interventions to improve adherence, such as simplified treatment regimens, text message reminders, education, and counseling, have had modest benefit (Reisner *et al.*, 2009b).

Mental health treatment for children and adolescents with HIV

There is some evidence that HIV-infected children have greater access to mental health treatment than HIV-affected children (Chernoff *et al.*, 2009; Gadow *et al.*, 2012; Mellins *et al.*, 2012). A study in the United States indicated higher rates of special education, psychopharmacology, and behavioral interventions in HIV-infected children (Gadow *et al.*, 2010). Psychiatric treatment may have decreased the prevalence of mental disorders in a longitudinal study of HIV-infected youth (Mellins *et al.*, 2012). However, intervention is needed for both HIV-infected and HIV-affected youth (Malee *et al.*, 2011; Gadow *et al.*, 2012; Mellins *et al.*, 2012).

Although there are very few investigations of mental health treatment in HIV-infected youth, psychiatric treatment, including psychotherapy and psychopharmacology, is common among HIV-infected children and adolescents. Although

more systematic studies of treatment effectiveness among HIV-infected and HIV-affected youth are needed, case series and other observational studies suggest similar efficacy and side effect profiles among children and adolescents with HIV who were prescribed antidepressants (Caballero *et al.*, 2005) and stimulants for ADHD (Sirois *et al.*, 2009).

Freudenreich and colleagues surveyed psychiatrists who specialize in the treatment of patients with HIV for their recommendations regarding psychopharmacology and psychotherapy in adults with HIV/AIDS (Freudenreich *et al.*, 2010). One must be mindful of interactions between psychiatric and antiretroviral medication (Thompson *et al.*, 2006). Although this work was not with children, these treatments are generally applicable to children and/or adolescents.

Interestingly, there are also a number of important interactions between HIV medications and illicit substances. Although there is no clear interaction between alcohol, heroin, or cocaine and antiretrovirals, induction of methadone and inhibition of amphetamine and methylenedioxymethamphetamine (MDMA or “ecstasy”) has been associated with antiretroviral treatment (Thompson *et al.*, 2006). Moreover, it has been shown that efavirenz, one antiretroviral treatment, is abused for its psychoactive effects (Inciardi *et al.*, 2007), and this form of substance abuse was reported among South African children (Grelotti *et al.*, 2014).

Psychiatric hospitalizations are more common in HIV-infected youth than in the general population and in HIV-exposed but uninfected children (Hein *et al.*, 1995; Gaughan *et al.*, 2004). Mood disorders and behavioral disorders are the most likely reason for hospitalization (Gaughan *et al.*, 2004). In prior studies on this topic, children aware of their HIV status and those who experienced a significant life event were more at risk (Gaughan *et al.*, 2004).

Resilience in children, adolescents, and families affected by HIV/AIDS

The mental health and well-being of children and adolescents affected by HIV/AIDS involves multiple ecological levels—from individual factors, to the family, peer group, and the larger community and culture. Each nested level presents risks (Lazarus & Folkman, 1984; Betancourt & Khan, 2008) as well as sources of potential protection and resilience (Bronfenbrenner, 1979; Ungar, 2011). While the available literature discusses physical, cultural, and community factors influencing the environments in which HIV-infected and -affected children grow and develop, there remains a much greater focus on risk than resilience. Furthermore, strong quantitative studies in diverse cultural settings are lacking.

Individual factors promoting resilience

Research in a variety of settings has documented important associations between coping strategies, mental health, and resilience in HIV-positive and HIV-affected children and

adolescents. In a longitudinal investigation of HIV-affected children in the United States, coping self-efficacy was significantly associated with child resilience, and resilient children demonstrated steeper declines in depression over time (Murphy & Marelich, 2008). HIV-infected adolescents in South Africa reported that goal-setting helped them to cope with their diagnosis (Petersen *et al.*, 2010). Negative coping styles have been observed to contribute to poor mental health outcomes. For instance, passive coping (e.g., blaming, wishful thinking, withdrawal, and self-criticism) was more frequently used by adolescents reporting medication-related stressors and was associated with greater depression (Orban *et al.*, 2010).

Self-esteem and hope for the future

Qualitative studies in Rwanda (Betancourt *et al.*, 2011a) and Uganda (Harms *et al.*, 2009) independently categorized perseverance and self-esteem as defining characteristics of resilience. The Rwandan constructs were originally expressed in local terms (*kwigirira*, *ikizere*, and *kwihangana*) assuaging concerns about imposition of external or Western constructs on these settings. One quantitative study found that non-HIV-affected children scored higher on self-esteem, positive future expectations, hopefulness about the future, and perceived control over the future, compared with children affected by HIV (Fang *et al.*, 2009).

Family-level factors for HIV-affected and HIV-positive children

Positive family processes are a critical source of protection in the mental health of children affected by HIV. Family functioning is often massively disrupted by HIV, increasing fear, blame, conflict, and poor communication. These family processes may raise risks for mental disorders in children directly and indirectly affected by HIV. In particular, the parentification of HIV-affected children increases risks for negative outcomes while positive parental bonds reduce emotional distress in HIV-affected adolescents (Stein *et al.*, 1999; Rotheram-Borus *et al.*, 2005, 2006). Thus, family-based interventions have great promise for assisting HIV-affected children.

Family-based interventions might be most effective if they focus on improving caregiver–child relationships, communication, and parenting in the context of living with HIV. In a qualitative study of HIV-affected children in Rwanda, family unity (*kwizerana*) emerged as an important local resilience promoting construct, comprising indicators such as “living together in harmony,” cooperation, mutual respect, and strong communication (Betancourt *et al.*, 2011a). Additionally, a study in New York City observed correlations between positive family functioning, resilience, and lower likelihood of deviant peer affiliation, and substance abuse (Rosenblum *et al.*, 2005). By contrast, child abuse and children’s deviant peer affiliation were correlated with less resilient outcomes (Rosenblum *et al.*, 2005).

High levels of parental monitoring combined with positive parent–child relationship have been associated with higher resilience in children (Dutra *et al.*, 2000). The role of both

mothers and fathers has been documented as important to mental health and resilience in HIV/AIDS-affected children (Brook *et al.*, 2002). A father’s presence in the home was associated with adaptive coping in HIV-exposed/non-HIV-affected adolescents (Brook *et al.*, 2002). Aspects of the father–child relationship (availability, support, child-centeredness, and satisfaction with the child) and paternal coping strategies increased the likelihood that adolescents themselves would engage in adaptive coping.

Coping in response to parental disease progression

Parental disease progression/impairment has been linked to poor mental health in children. For example, decreases in child resilience have been associated with maternal viral load and disease progression (Murphy & Marelich, 2008). However, in a 6-year longitudinal study of 213 adolescents, while early parentification due to HIV/AIDS was associated with emotional distress, substance use, and conduct problems during the 6 months following death, parentified adolescents actually demonstrated more adaptive coping skills (including positive action and engaging social support) and less alcohol and tobacco use over time as compared to nonparentified HIV-affected adolescents (Stein *et al.*, 2007). Similarly, HIV-affected children in Kenya found that most depicted their role as caregiver in a positive light characterized by independence, problem-solving, and work ethic (Skovdal *et al.*, 2009).

Access to educational resources

A qualitative study of adolescents living with HIV in Brazil found that stigma and lack of social inclusion influenced adolescents’ willingness/ability to disclose HIV-status, and interfered with their access to community resources such as education and social support (Ayres *et al.*, 2006). Limited access to HIV information in turn increases adolescents’ risk for HIV. Research with Ugandan AIDS-orphans and caregivers found that disclosure and openness were often discussed in the context of resilience and self-efficacy, while silence, secrecy, and stigma contributed to feelings of self-hate, anxiety, hopelessness, and confusion among HIV-affected children (Daniel *et al.*, 2007). Similarly, findings from a mixed-methods study of adolescents in New York City suggest that a stigma-free social context and encouragement of family communication about HIV contributed to promoting adolescent resilience (Pivnick & Villegas, 2000).

Social support

The protective role of social support, including perceived financial, physical, and emotional help from family, friends, and the larger community, has been examined in several studies. For instance, among 703 AIDS-orphaned and nonorphaned children and adolescents in South Africa, perceived social support was associated with lower symptoms of PTSD at all levels of trauma (Cluver *et al.*, 2009b). In the United States, adolescents rated social support and problem solving among

the “most helpful” coping strategies; however, these strategies were not widely used (Orban *et al.*, 2010). Similarly, in rural China, tangible support from family predicted less depression and loneliness and more positive social interactions, while emotional support was associated with reduced delinquent behavior (Zhao *et al.*, 2011b).

Peer support

Among HIV-affected adolescents in New York City, positive peer affiliations and community interactions were correlated with less deviant peer affiliations, while peer deviance was associated with older age, community risk factors, and less resilience (Rosenblum *et al.*, 2005). Similarly, among South African AIDS-orphaned children, caregiving, contact with extended family, school/peer support, and positive activities emerged as key protective factors, while negative peer interactions such as bullying and gossip were identified as risks (Cluver & Gardner, 2007). These findings are consistent across multiple studies, indicating that positive interactions with peers and access to elders and psychosocial programs are emotionally beneficial.

Disclosure

Disclosure is an important element in accessing social support. However, protecting the confidentiality of those living with HIV is important to prevent stigma and discrimination. Disclosure should be managed carefully. Most people do not need to know the HIV serostatus of children or adolescents. It is useful for a small number of supportive people, both family and friends, to know the serostatus of the child for support and safety purposes. It is also usually helpful to have peers who are also living with HIV, to whom children, and particularly adolescents, can relate. In families, disclosure of a caregiver's HIV status is also an issue of importance. In recent work in Rwanda, we observed that caregivers often disclosed their HIV status to only certain children or had initiated a conversation without much information, resulting in confusion and anxiety. When children do not understand what it means for parents or caretakers to be living with HIV, misunderstanding and miscommunication can result and contribute to mental health problems such as depression and anxiety.

Among adults, HIV counseling and testing is an important risk-mitigation strategy and is related to safer-sex behaviors among HIV-infected persons (Weinhardt *et al.*, 1999). Despite recommendations that children learn their HIV-status, many children are not informed. Among the issues preventing parents from disclosing are guilt, stigma, and fear of loss. Caregivers reported higher oppositionality, anxiety, and dysthymia in children aware of their HIV status, but only dysthymia remained after adjusting for sex and caregiver factors (Gadow *et al.*, 2010). Children who were aware of their HIV status do report greater anxiety (Gadow *et al.*, 2010). However, as children age, becoming aware of their HIV status and the implications of

this for their own and others health is critical for appropriate adherence to treatment and prevention of transmission.

Implications for intervention research and clinical settings

Risk factors associated with HIV and mental health problems occur across each level of the social-ecology; thus, protective factors to build capacities and offset risks at each level are needed. Mental health treatment works; however, the literature on mental health treatment among children and adolescents living with HIV is sparse. While many empirically supported mental health interventions such as cognitive behavioral therapy (CBT) or interpersonal psychotherapy (IPT) exist for children and adolescents in the developed world, few have been adapted to address the context of HIV infection. Furthermore, culturally adapting and delivering interventions in the native language of patients and with clinicians from similar cultural backgrounds increases efficacy (Griner & Smith, 2006).

On the other hand, public health interventions aiming to reduce HIV transmission have rarely addressed mental health issues that contribute to sexual risk behavior and poor adherence to medical care. An exception is the intervention CLEAR (“Choosing Life: Empowerment! Action! Results!”), which specifically targets HIV-positive substance abusing adolescents and young adults (Rotheram-Borus *et al.*, 2004).

Research has shown that individual interventions can have great success in changing high-risk sexual behavior (Malow *et al.*, 2007). A meta-analysis of 98 sexual risk reduction behavioral interventions targeting adolescents revealed that interventions were relatively successful in increasing condom use, reducing incident sexually transmitted infections (STI)s, reducing or delaying penetrative sex, and increasing negotiation skills for sexual safety (Johnson *et al.*, 2011). However, a meta-analysis of 28 interventions for adolescents in South Africa revealed no significant effect on reducing sexual behavior or HIV incidence, and an increase in condom use at last sexual encounter only among males (Michielsen *et al.*, 2010). This suggests that interventions in LMIC may need more adaptation and greater attention to forces that contribute to sexual risk at different levels of the social ecology.

The focus of the majority of interventions for children and adolescents has been on sexual risk reduction among those at risk for HIV. Fewer interventions have focused on those living with or affected by HIV. Among these, individual interventions targeting skill building have been shown to be effective. For Example, participants in the Healthy Choices motivational enhancement intervention were found to have greater reductions in viral load, number of unprotected sexual acts, and less frequent substance abuse (Naar-King *et al.*, 2006, 2010).

Successful Western intervention programs have also been adapted for international purposes. The youth intervention CLEAR (Rotheram-Borus *et al.*, 2004) was culturally adapted

for use in Uganda and was associated with greater condom use and fewer sexual partners (Lightfoot *et al.*, 2007). Similarly, a pilot adaptation of an intervention targeting HIV-affected individuals, the Healthy Living Project, was adapted for youth in Kinshasa, Democratic Republic of Congo and showed significant increase in protected sexual acts (Parker *et al.*, 2013). These results suggest that intervention programs can be tailored to meet culturally specific needs of various populations.

Group interventions for children and adolescents living with HIV

Group interventions are the most common type of HIV intervention and have been found to reduce risky health behaviors (Malow *et al.*, 2007). Successful interventions often incorporate theories such as the social action theory and cognitive behavioral theory into their curricula. Groups can offer flexibility and interaction between participants, allowing for opportunities for discussion and role-play on social norms and practices.

An example of a successful group intervention is “Together Learning Choices.” (Rotheram-Borus *et al.*, 2001). The intervention comprises of two modules, “Stay Healthy” and “Act Safe,” and an optional module, “Being Together.” The “Stay Healthy” module discusses coping with HIV, implementing healthy daily routines, and participating in health care decisions; the “Act Safe” module discusses reducing substance abuse and unprotected sex and identifying risk behavior triggers; and the “Being Together” module emphasizes quality of life and improving emotional well-being. The intervention significantly decreased unprotected sexual acts, number of sexual partners, and substance abuse among intervention participants.

Family-based interventions

Negative family dynamics, including intimate partner violence and aggressive parenting, compromise children’s ability to establish positive peer or romantic interactions (Capaldi & Clark, 1998; Gilliom *et al.*, 2002). Interventions targeting families made vulnerable by HIV hold great promise (Richter *et al.*, 2005; Betancourt *et al.*, 2011b). For example, *Collaborative HIV Prevention and Adolescent Mental Health* (CHAMP) is a prevention program promoting resilience through educational and skill building activities to increase understanding of HIV, encourage caregiver–child communication, and improve social problem-solving abilities. The CHAMP program was shown through large-scale trials in the United States to be effective and successful adaptations of the program were implemented in South Africa and Trinidad (Baptiste *et al.*, 2006; Bhana *et al.*, 2010).

The *Family Strengthening Intervention* (FSI) for children living in families affected by HIV in Rwanda is prevention oriented and involves the entire family. The FSI is based on the Family-Based

Preventive Intervention (FBPI), one of the earliest programs to adopt an ecological approach to enhancing resilience in the context of chronic family illness (Beardslee, 1998).

Together for Empowerment Activities was designed to improve social support and reduce depression for people living with HIV and their families in China (Li *et al.*, 2011). It emphasizes the interdependence of participants and how relationships among family members can have a positive or a negative impact on an individual’s health. Organized into three separate modules broadly covering health, relationships, and personal quality of life, each module is further broken down into a series of small group discussions, family activities, and community activities intended to increase social support for people living with HIV and their families.

Economic strengthening interventions

The loss of parental economic support and the increasing number of orphans in Sub-Saharan Africa create significant economic burden (Ssewamala & Ismayilova, 2009; Ssewamala *et al.*, 2010). The *SUUBI* Project utilizes a family-based economic strengthening model to support children orphaned by HIV in Uganda. Orphans’ caregivers are empowered to partner with local organizations, including financial institutions, to save money for the children’s postprimary education or to finance the start of a small family business. The intervention works in three parts: workshops in asset-management, peer mentoring, and a child savings account. This intervention led to a decrease in the sexual risk-taking intentions of the children and an observable improvement in school performance (Ssewamala & Ismayilova, 2009).

Community level interventions addressing stigma

For many HIV/AIDS-affected children and families, navigating community stigma remains a very challenging issue. In many settings, social support and social stigma may co-occur. For instance, in Zimbabwe, some children cited family and community support as a positive resource, while others reported experiencing maltreatment from adoptive family members (Wood *et al.*, 2006). Many children expressed a desire to share thoughts and worries, but this went against cultural norms that perseverance and “not breaking down” are the most positive ways to cope.

Community sensitization campaigns and peer-to-peer education have high potential for raising community awareness and combating stigma (Sayson & Meya, 2001). A youth-led community intervention in Tanzania was successful in enhancing positive attitudes toward youth as change agents and spreading HIV risk reduction knowledge (Kamo *et al.*, 2008). Family-based interventions can also contribute to dispelling

internalized stigma within the family through open discussion about HIV (Betancourt *et al.*, 2011b, 2013, 2014). Interventions are needed to teach children how to talk to trusted friends and seek support from leadership in the community. Since stigma from peers can be particularly detrimental to children living with and affected by HIV, peer-to-peer support programs and school-based awareness-raising programs have the potential to combat stigma at the level of the school or larger community ecology (Kennedy *et al.*, 2004).

Recommendations

Research on promoting mental health and resilience in children affected by HIV is critically needed, particularly in the global South where the disease burden is high but research attention is limited. Children and adolescents infected with or affected by HIV experience numerous problems, such as internalizing and externalizing behaviors, depression, and poor self-esteem. However, these problems can be attenuated through treatment, supportive programs, and skill development (Funck-Brentano *et al.*, 2005; Rotheram-Borus *et al.*, 2006; Kumakech *et al.*, 2009). Thus, there is need for intervention research that promotes resilience and positive outcomes across all ecological levels.

The development of sustainable and resource efficient HIV and mental health prevention programs is a key research and practice objective. Unfortunately, prevention is rarely perceived as a priority in settings with numerous pressing health care problems. However, in resource limited settings, prevention of mental health problems is critical given limited economic resources, trained mental health care providers, and access to both ART and psychopharmacology medication (Patel *et al.*, 2007a).

A second research and practice objective is to successfully adapt, scale-up, and implement key efficacious interventions in appropriate clinical and community settings (Patel *et al.*, 2007b; Kieling *et al.*, 2011). A number of efficacious interventions have been developed. However, work to implement these interventions and programs with fidelity in practical settings, or to adapt them for LMIC, has been limited to date.

A third research and practice objective is increasing the competence and reach of mental health service systems. This includes task-shifting approaches to train nonspecialists to provide basic mental health services, strengthening programs that train new mental health workers, and building the competence of existing workers to work with children and adolescents in the context of HIV infection (Kakuma *et al.*, 2011). Reach can be increased through integrating mental health care into other child- and adolescent-focused services such as schools, HIV care, pediatric, and primary health care. Finally, efficient use of resources can be obtained through assessment and outcome monitoring, appropriate triage and referral, and stepped-care approaches (Patel *et al.*, 2007b; Beaglehole *et al.*, 2008).

Fourth, culturally appropriate, psychometrically and clinically sound assessment and evaluation approaches for monitoring outcomes, guiding clinical decision-making, and continuous quality improvement are needed, as are efficient and practical approaches to supervision, capacity building, and technical assistance (Beaglehole *et al.*, 2008). This is not limited to LMIC; integrating mental health care into existing HIV services in any setting should include program evaluation and may require technical assistance, developing or adapting measures and benchmarks, and provider and staff training and supervision.

In conclusion, applying a social ecological framework to understanding risk and protective processes in the mental health of children and families affected by HIV/AIDS identified key leverage points for both prevention and intervention in a manner that is holistic, systematic, and responsive to the complex nature of risks and resilience. An important focus for research is to concentrate on modifiable processes that contribute to resilient outcomes. By addressing these gaps in the evidence base, future research can strengthen our understanding of appropriate targets for promoting mental health and resilience in children and families affected by HIV/AIDS.

Children with specific sensory impairments

Naomi Dale and Lindsey Edwards

Great Ormond Street Hospital, NHS Foundation Trust, London, UK

Children without vision and hearing, the dominant senses for accessing the environment, face severe disadvantages. Some children follow compensatory developmental trajectories and even develop exceptional abilities; others advance with great difficulty. This chapter describes the impact of visual impairment (VI) and hearing impairment (HI) on child development, with a focus on vulnerable developmental processes and psychiatric risk.

Visual impairment (VI) refers to all degrees of vision reduction, where reduced acuity is defined as vision clarity. For the purposes of international comparison, the US legal definition of blindness is best-corrected visual acuity of less than 6/60, (being able to see at 6 metres what someone with normal vision can see 60 metres away). Snellen notation is now being replaced by the logMar system where logMar 1.0 is equivalent to 6/60. The UK legal definition of blindness is 3/60 or less vision and partial sight as 6/60 to 3/60. Hearing impairment (HI) is defined by the quietest sound that can be heard in decibels across a range of frequencies. According to the UK system, severe hearing loss is the inability to hear sounds quieter than 65–70 decibels (dB) and profound loss at 85–90 dB. Individuals who cannot hear these sounds are unable to hear speech adequately even when using hearing aids.

Visual impairment

The two main types of childhood visual impairment (VI) are *peripheral or ocular* and *cerebral*, although a “mixed” condition is possible. The former arises from abnormalities of the eye globe, retina or anterior optic nerve, and the latter originates in the posterior optic nerve, optic radiations and visual cortex. Peripheral visual disorders can be divided into “simple” or “isolated,” where VI is the only impairment, and “complex” or “syndromic,” occurring in a wider syndrome. Estimate of the incidence of childhood VI is 4 per 10,000 infants in the first year, rising to 5 per 10,000 at 16 years in the UK (Rahi *et al.*, 2003).

Over three quarters of children with VI in the United Kingdom have additional non ophthalmic disorders including intellectual disability, motor disorders, hearing impairment (HI), epilepsy, autism, attention deficit hyperactivity disorder (ADHD) and health impairments. These reduce to about 20% in children with “simple” congenital VI. Children with cerebral visual disorders have wide ranging visual disturbances and commonly additional brain difficulties. Cerebral vision-processing deficits occur in many conditions: cerebral palsy, Fragile X and Williams syndrome. One in 10 people with intellectual disabilities in the United Kingdom are estimated to have a VI.

Etiology, identification, and visual management

The numerous causes of VI often accompany wider disabilities in high income countries. In the United Kingdom, the most common anatomical sites of origin are cerebral visual pathways (48%), the optic nerve (28%) and the retina (29%). “Isolated” or peripheral visual disorders are associated with prenatal congenital causes, for example, anophthalmia, Leber’s amaurosis, corneal anomalies and “complex” syndromic conditions like Joubert syndrome, with increasing knowledge of the genetic anomalies involved. Cerebral visual impairment (CVI) has many causes from prenatal, perinatal, neonatal and childhood factors, including injury, vascular pathology, focal tumors, and infections.

Apart from overt eye defects at birth, parents often first notice that their baby is not looking at them or tracking their movements. Once ophthalmologists and paediatricians have determined the cause of poor visual responses, standard visual function tests are available. Three quarters of childhood visual disorders leading to VI in the United Kingdom are neither preventable nor treatable. For most, treatment provides vision aids for those with sufficient visual capacity. Prompt identification and treatment are essential as infants may have the potential to develop useful vision with interventions applied under 1 year of life. The long-term goal of habilitation is to increase participation in everyday living, regardless of reduced vision abilities.

Early family support and intervention

During the early period of diagnosis, parents often feel isolated, confused and distressed. They require support, information and guidance in maximising their baby's development and vision. Parents are dealing with an unfamiliar developmental pathway, and informed guidance will give them normative expectations to anticipate and optimize their infant's next developmental steps. Some early interventions exist, though their effectiveness has not been fully evaluated. The so-called, widely used Oregon method extends the Portage system. The Early Support Developmental Journal for infants with VI, a parent oriented set of materials, provides one of the main intervention frameworks in the United Kingdom and is currently undergoing evaluation (Dale *et al.*, 2007).

Developmental aspects of visual impairment

As much of learning in infancy is vision-based, poor vision can profoundly affect development without intervention. Infants are very reluctant to feel and explore their physical environment, and auditory-directed reaching occurs later than visually directed reaching. Delays in sensorimotor and cognitive development are common, with the greatest vulnerability occurring in profound VI (Dale *et al.*, 2002).

The earliest language milestones are often delayed. Quality of maternal responsiveness, control, and goal setting behaviors are positively related to the young child's advances in language skills, exploration of the environment and sensorimotor development (Hughes *et al.*, 1999). As vocabulary expands, syntax and grammar also begin to normalise. However, language may be more formulaic with expressive ability outstripping semantic understanding. Pragmatic or social use of language can also lag behind, with difficulty in adapting language to the social context including early pronoun use.

Educational attainments

By school years, some children with VI will reach or exceed the verbal IQ of their sighted peers. Growing cognitive capacity can support superior learning in some instances. Nearly three quarters of VI children in the United Kingdom are educated in mainstream settings. Depending on level of vision, children are introduced to Braille or enlarged print (or both) for reading. However, they may struggle to keep up with the mainstream curriculum. By 7 years, Braille readers lag behind their sighted peers in reading and writing (Harris *et al.*, 2012). Children with low vision levels may read enlarged print more slowly. By 13–16 years adolescents may be up to 3 years behind their peers in attainment skills including mathematics though more specialized academic support or helping parents feel confident in supporting their child's reading or mathematics could accelerate progress (e.g., Giesen *et al.*, 2012).

Emotional development and psychological well-being

Following Selma Fraiberg's (1977) seminal work, there was concern about the passivity and self-centredness of the infant with profound VI. However, other work suggests that reciprocity is possible between infants and their parents (e.g., Preisler,

1995). Children can develop secure, albeit at times delayed, attachment, continuing into adulthood (Ardito *et al.*, 2004). However, this process is especially vulnerable when the parent struggles to "tune in" to a more unresponsive baby. The clinical context and support of parents can influence infant bonding (Rahi *et al.*, 2005).

Beyond infancy, the ability to recognize emotions develops slowly though it is debated whether this is part of a general or specific delay (Dyck *et al.*, 2004). In contrast to children with HI, emotional recognition is more vulnerable than emotion understanding and vocabulary, which are more verbally mediated processes.

One of the greater challenges for children with VI is social integration. They may desire friends but lack necessary skills and be restricted from playground activities due to fears of safety or bullying. Adolescents may spend more time alone, have smaller social networks and lower social skills and self esteem—with further risk if the parents are overprotective or the young person is introverted, particularly for boys (Pinquart & Pfeiffer, 2011). However, some young people are resilient, and research suggests that these VI children may exhibit self-esteem that is similar or higher than that in sighted peers (Kef and Deković, 2004; Lifshitz *et al.*, 2007).

Young people with VI face difficulty with everyday tasks. Some studies suggest a lower health-related quality of life (Chadha and Subramanian, 2011), though others find no differences from sighted peers (Wong *et al.*, 2009). A more VI child centered approach is needed to capture the subjective perspective (Rahi *et al.*, 2011). Unfortunately, quality of life may decline with increasing age and greater degree of VI possibly because of unwelcome dependency, increasing isolation and limited employment prospects.

Social processes are particularly vulnerable areas. This can be partly compensated for by parents adapting their interactive routines to ensure that infants enjoy social games and vocal interactions. However, delays in social communication development may continue across the early years, particularly in children with profound VI, and these are greater than in HI.

As infants with VI cannot follow their parent's gaze behaviors or point out things of interest, "joint attention" skills are especially vulnerable (Bigelow, 2003). Even low levels of "form" vision greatly enhance opportunities for object-centred "joint attention" (Dale *et al.*, 2013). Possibly to compensate, parents tend to resort to higher physical and verbal involvement and control of activities which may be more or less adaptive for the child (Moore & McConachie, 1994).

As language skills develop, parents use "mental state" language to help their child understand other people's emotions, beliefs, and intentions (Tadić *et al.*, 2013). The question of whether theory of mind (ToM) is fundamentally limited by lack of vision is strongly debated. Delay occurs in first order "false belief" tasks like the Sally Ann task, which are traditionally visual, with the reported age of acquisition varying from 7 to 12 years (Green *et al.*, 2004; Brambling & Asbrock, 2010). Advanced ToM skills (i.e., awareness that other people have

beliefs about beliefs) may possibly emerge more similarly to sighted children, at least in children with a wider range of congenital visual impairment, and appears associated with age and verbal intelligence (Pijnacker *et al.*, 2012).

Neuropsychological processes

School-aged children with VI vary in their “higher order” cognitive processes including attention, working memory, and executive functions. In the clinic context, neuropsychological assessment commonly reveals uneven strengths and weaknesses in school-aged children. For instance, some children are notably weak in tactile or spatial perception, affecting their potential for independent navigation, object manipulation, search strategies, and Braille reading (Gori *et al.*, 2010). Those with the greatest difficulty in attention shifting in the preschool years show more behavioral rigidity and weaker executive function by 6–12 years (Tadić *et al.*, 2009; 2010). Of concern, this subgroup also shows weaker adaptive behavior functioning, which could jeopardize future independent living and employment. In children with cerebral visual impairment, specific weaknesses may be identified in “dorsal stream” processes, such as visual-motor coordination, visual/spatial perception, and visual attention.

Neuroplasticity and brain organization

With the large occipital lobe of the brain under-utilized, the brain migrates nonvisual functions into this area—highlighting the “cross plasticity” of the visual cortex. Behavioral, functional neuroimaging, and electrophysiological studies have shown that adults with congenital blindness activate the visual cortex for Braille reading and other tactile tasks. Auditory motion perception activates visual motion areas of the cortex and semantic linguistic processing occurs in the primary visual cortex (Amedi *et al.*, 2004). Other neural functional networks do not migrate elsewhere and appear amodal; adults with congenital blindness use similar brain regions as sighted adults to reason about mental states (e.g., medial prefrontal cortex) (Bedny *et al.*, 2009). Increased capabilities are found in auditory perception (sound localization, pitch discrimination), speech processing, biographical memory, and associative learning (e.g., Föcker *et al.*, 2012; Withagen *et al.*, 2013). The brain is highly plastic early in life but is more resistant to subsequent experience later on; for instance tactile reorganization does not occur in adults with late onset blindness after 16 years (Sadato *et al.*, 2002).

VI and complexity

Assessment and diagnosis of neurodevelopmental disorders

Even in children with “isolated” peripheral visual disorders, advancing genetic knowledge highlights that ocular genetic mutations (e.g., SOX2) are also expressed in the brain and neurodevelopmental prognosis is variable. Disorder at peripheral or primary visual cortex level may be associated with changes in white matter and “higher” visual processing pathways (Atkinson & Braddick, 2011; Webb *et al.*, 2013). Profound visual impairment is a further risk factor; a third of infants are at risk of regressing or plateauing in their development in their

second year of life, a phenomenon described as “developmental setback.” Early behavioral signs emerge between 16 and 27 months, suggesting a critical developmental period. Infants who may have been very responsive in their first year of life show increasing self-directedness, social avoidance, temper tantrums, loss of first words, echolalia or mutism and nonfunctional repetitive actions and stereotypies. These behaviors tend to persist and the chronic disorder generally leads to a later clinical diagnosis of autism. Other risk factors include higher number of brain lesions, male gender, and severe intellectual difficulties (Cass *et al.*, 1994; see review by Sonksen & Dale 2002). Developmental setback is likely to be the most severe manifestation of an autistic spectrum disorder (ASD) in children with VI.

A great clinical challenge to differentiating a chronic ASD in children with VI is that, in the early years, many children with VI show autistic like difficulties. Behavior features like echolalia, self-directed behavior, stereotypies, communicative difficulties, and obsessional restricted interests are common in the preschool period. The long-term outlook for children presenting with ASD features is variable. In some children, the traits reduce significantly as the child develops more adaptive social behavior, language and communication—described as “reversible autism” (Hobson & Lee, 2010). For a substantial subgroup, chronic difficulties persist and it is their continuity and intensity by 4–6 years and older that should alert the clinician to a possible ASD (Absoud *et al.*, 2010) (see Chapter 51). Even milder presentations can have a severe disabling impact in the context of visual impairment.

Current estimates are of 11–20% with clinical autism in heterogeneous populations, with higher incidence in lower IQ and more severe VI—rising to 30% in profound VI (Brown *et al.*, 1997; Fazzi *et al.*, 2007; Mukaddes *et al.*, 2007). Up to 60% of VI children are rated with at least one area of difficulty in social communication/restricted behaviors (Pring & Tadić, 2005; Parr *et al.*, 2010). Careful monitoring across the preschool and primary school years and caution against reaching premature diagnostic conclusions is recommended. Assessment of “higher” vision, intellectual, motor, or ASD impairments in children with vision disorders is very challenging and requires highly specialized expertises in VI and paediatric neurodisability to carry out a differential diagnosis within an “informed” developmental framework (Sargent *et al.*, 2010).

Psychological and psychiatric issues

There is limited knowledge of the prevalence of psychological or psychiatric difficulties in children with VI, but high rates of behavior difficulties (50–70%) have been reported in representative studies (Jan *et al.*, 1977; Tirosh *et al.*, 1998). Of these, anxiety disorders, oppositional disorder with or without attention deficit hyperactivity and avoidant disorder with or without stereotypy are rated most frequently. Some studies find no difference in psychosocial adjustment and well-being between adolescents with VI and their sighted peers, but other studies point to a higher risk of psychological difficulty including depression (Koenes & Karshmer, 2000; Huurre *et al.*, 2001; Pinquart & Pfeiffer, 2013). Risk factors include having additional

disabilities, receiving less parental emotional support, being isolated and lacking friends, being female, experiencing bullying, and having lower self-esteem. As in sighted peers, older adolescents are more at risk of psychological difficulties. Higher functioning young people may show considerable resilience, drive, and motivation but raised anxiety and emotional stress are often reported by parents and educators.

Parental well-being and support for parents is an important factor in their ability to cope and support their child; parenting stress and depression and its effects on interaction are likely to be high risk factors. Behavior problems are a high source of stress in parents, especially if the child has high caregiving demands and multiple disabilities (Tröster, 2001).

Young children with VI are often referred to the clinic with behavior difficulties including attention difficulties, temper tantrums, and aggression. Formulations need to account for the impact of VI on behavior and development (and the family) and tailored intervention may include psycho education for parents and teachers, behavioral interventions and strategies to enhance compensatory function and developmental growth. With obsessional interests and self-directed behaviors, parents find it very difficult to influence or help regulate their child's behavior, attention focus, or mood. The shared risk for autism or intellectual disability warrants a full clinical exploration before formulating an intervention plan which draws on principles used for children with autism but adapted for VI. This includes managing the environment, promoting the child's effective communication and supporting their sensory needs.

Anxiety disorders can occur across the age range, particularly in children with ASD tendencies. Young people with VI may be more prone to fears and phobias of potentially harmful situations (Ollendick *et al.*, 1985). Interventions may draw on psycho education, environmental restructuring, goal planning, and behavior modification with parents and educators and also therapeutic approaches including cognitive behavioral therapy (CBT), narrative therapy, or solution-focussed therapy with older children and their families.

Sleep disorders are common in children with VI, with a significant impact on the health of the children and causing distress to their caretakers (see Chapter 70). Sleep hygiene and behavioral approaches may be successful but with unresponsive sleep disorders, improved sleep latency with melatonin has been demonstrated in some cases (Khan *et al.*, 2011). Severe and unpredictable behavior (aggression, self injury, oppositional defiance and temper outbursts) is found in children with combined visual impairment, autism and intellectual disability, and commonly in septo-optic dysplasia with midbrain defects and hypo-pituitarism. A tailored behavioral intervention approach with strategies to support emotion self-regulation is recommended and pharmacological assistance may also be indicated in complex resistant behavior profiles.

Hearing impairment

The two main types of childhood HI are conductive and sensori-neural, although it is possible to have a "mixed"

loss. The former, usually resulting from otitis media, may be transient. Permanent conductive hearing loss occurs in many syndromes associated with middle-ear disruptions, such as congenital cholesteatoma. Sensori-neural hearing loss, typically caused by abnormally functioning cochlear hair cells, can be congenital, progressive, or sudden, with an estimated incidence around 1–3 per 1000 live births or 0.3% of all school children (www.patient.co.uk). More than 90% of deaf children are born to two hearing parents. A third hearing disorder is Auditory Neuropathy/Auditory Dys-synchrony (Berlin *et al.*, 2001). The prevalence in children is not known, but it is thought that this condition is present in approximately 1 in 10 children with HI; the children characteristically have poor speech-perception abilities relative to their degree of HI. All types of hearing loss, including as a result of otitis media with infusion, can negatively affect language development. However, less impact occurs in deaf children of deaf parents who are raised within the Deaf culture and use British Sign Language as their means of communication, depending nevertheless on whether the child has additional disabilities or not.

Etiology, identification, and audiological management

The primary cause of permanent HI in children is genetic anomalies, accounting for approximately 60% of cases. In 70–80% of these, HI is the only impairment, for example, Connexin 26 mutation. Up to 30% of genetic HI is syndromic, with over a hundred known syndromes, most associated with sensori-neural hearing loss. Small proportions of childhood HI are due to infections such as toxoplasmosis, bacterial meningitis, cytomegalovirus, and rubella infection, severe prematurity or neonatal complications and ototoxic drugs such as streptomycin. A variety of tests are used in the identification of HI, from shortly after birth (Newborn Screening) through early childhood. Once a permanent HI is confirmed, assistive hearing devices including hearing aids, cochlear implants, and bone-anchored hearing aids aim to optimize access to and clarity of the speech signal. A recent more controversial intervention is a prosthetic auditory brainstem implant as its effectiveness for improving speech and language is unproven (e.g., Goffi-Gomez *et al.*, 2012).

Cochlear implantation is the treatment of choice for severe to profound congenital HI and also for progressive or acquired losses after language has developed. Cochlear implantation (particularly bilateral implantation) has positive effects on speech perception and production, language, and reading skills. Superior outcomes are associated with early implantation, particularly in the first 2 years of life (see Forli *et al.*, 2011 for a review). However, there remains great variability in outcome.

Early family support and intervention

Probably the single largest impact on developmental outcomes for children with HI has been Universal Newborn Hearing Screening, fully implemented across the United Kingdom in 2006. The majority of sensori-neural hearing loss is identified

by 2 months of age and amplification or implants should be introduced promptly. Once permanent HI is identified, active involvement of parents in maximizing opportunities for learning through everyday interactions is essential for optimizing speech and language development. Early identification and intervention has been associated with better speech, language, and academic outcomes (e.g., Fulcher *et al.*, 2012).

Possible language interventions range from fully visual-manual to fully auditory-oral, with sign and speech combinations (e.g., sign-supported speech, simultaneous communication, cued speech, and total communication) (Stredler-Brown, 2010). Once an approach has been selected, family members must become proficient in that approach so that the child has access to a complete language model. Effective communication in early childhood is likely to be protective against future emotional and behavioral problems.

Developmental aspects of hearing impairment

Specific cognitive abilities, such as memory and attention, may be adversely affected by HI, and these skills are better predictors of the difficulties of learning language than IQ in children with HI (Marschark & Hauser, 2008).

HI is strongly associated with delays in receptive and expressive language skills and speech intelligibility. Most children with HI have smaller vocabularies and poorer use of grammar than their hearing peers, especially in the early years (e.g., Blamey, 2003). The rate of spoken language development is not strongly dependent on the degree of hearing reduction because other factors such as age of provision of hearing device, educational factors, other abilities and family support are all influential.

Educational attainments

A sound spoken language base is essential for learning to read, therefore many children with HI are at a significant disadvantage. Kyle and Harris (2010) found the gap between the reading scores of HI and hearing children widened from 1-year at 8 years to 3-years at 11 years. Even with the advantage of better access to spoken language afforded by cochlear implants, only a minority (less than 20%) of children with HI have a reading age within 12 months of their chronological age (e.g., Harris & Terlektsi, 2011; Dillon *et al.*, 2012). Much less is known about mathematical achievement but the evidence suggests that it is often significantly compromised (Qi & Mitchell, 2012) and cochlear implants only partly ameliorate the impact of HI. Word-based mathematical problem-solving relies more on reading comprehension and particularly disadvantages children with HI (Edwards *et al.*, 2013).

Emotional development and psychological well-being

Preschool-aged children with HI frequently exhibit high levels of frustration. Toddler tantrums often extend beyond the expected age period for hearing children, particularly when effective age-appropriate communication is lacking and language development is delayed. Some young children with HI

appear excessively shy and avoid interacting with people outside their immediate family. Childhood HI has a significant impact on family communication patterns and dynamics but little is known about the impact on the attachment relationship between mother and infant. Most children do develop close attachment relationships with their parents, and deaf children of deaf parents show similar attachment patterns to hearing children of hearing parents in the Strange Situation Paradigm according to Meadow-Orlans *et al.* (1983). However a higher incidence of avoidant and resistant classifications is observed between deaf children and hearing mother dyads compared with hearing dyads (Spangler, 1987). As in infants with VI, reactions to the diagnosis of HI and degree of support perceived by the parent appear to be important in influencing early bonding with the infant.

In school-aged children with HI, disruptions may occur in the development of empathy and processing of emotions including facial expressions (e.g., Bachara *et al.*, 1980; Ludlow *et al.*, 2010). Consequently many children with HI experience difficulties in establishing and maintaining positive peer relationships. Social competence and the quality of interactions between HI and hearing children are partially dependent on school setting (mainstream versus special education) and are associated with self-esteem and are often negatively impacted by language and communication delays (Antia & Kriemeyer, 2003; Martin *et al.*, 2011). Children with HI are sometimes rejected by their peers and experience victimization or bullying, leading to lowered self-esteem, and emotional and behavioral problems (van Gent *et al.*, 2011; Kouwenberg *et al.*, 2012).

From the earliest days, parent-child interaction shapes the development of prelingual social communicative behaviors such as visual attention and eye contact, joint attention, turn-taking, and the use of facial expressions to support the meaning of verbal information. Research suggests that some, but not all aspects of these early interactions may develop differently in HI children with hearing parents (e.g., Gale & Schick, 2009; Nowakowski *et al.*, 2009).

Development of mentalizing skills in children with HI is significantly delayed, as in those with VI. Children typically fail to pass first order ToM tasks, which are characteristically mastered by hearing 3–4 year olds, until they are aged 13 years and even beyond (e.g., Russell *et al.*, 1998). The ability is strongly related to the language and communicative competency of the child, whether in spoken or sign language; notably, deaf children of deaf parents do not demonstrate such delays (e.g., Meristo *et al.*, 2007). Little or no delay in ToM follows early cochlear implantation when this is associated with improved spoken language proficiency (Rommel & Peters, 2009). Early conversational input about the beliefs and mental states of others is therefore crucial for fostering adaptive social-cognitive development. Unfortunately, parents of deaf children often find it extremely challenging to modify their use of language and communication to meet the changing needs of their child through infancy and childhood. Compensatory strategies such

as establishing eye contact before speaking, “scaffolding” the child’s attempts at producing spoken words or phrases and using a “sign sandwich” when necessary (saying the target word, signing it, then saying it again) usually need to be explicitly taught to parents by teachers of the deaf or speech and language therapists from the earliest days.

Neuropsychological processes

The “higher-order” cognitive processes comprising executive function abilities are vulnerable in children with HI. Deficits in working memory are consistently found in those with and without cochlear implants (e.g., Pisoni *et al.*, 2008), and deficits in attention control, particularly visual attention and selective attention are common but peripheral attention may be enhanced (Dye *et al.*, 2008). Studies exploring other executive functions generally indicate greater impulsivity and difficulties in problem-solving, sequencing, and planning compared with hearing children (e.g., Hauser *et al.*, 2008; Edwards, 2010; Pisoni *et al.*, 2010). The development of all these functions is closely linked with language skills (e.g., Figueras *et al.*, 2008).

Neuroplasticity and brain organization

In the absence of auditory input, thalamo-cortical areas of the brain and the auditory cortex become utilized by other sensory modalities, particularly the visual modality, showing “cross-modal plasticity” (Bavelier & Neville, 2002; Gordon *et al.*, 2011). In children with HI increased capabilities and compensatory skill in nonauditory modalities have been demonstrated, for example, enhanced tactile accuracy, visual attention, and processing of stimuli in the peripheral visual field (Neville & Lawson, 1987; Bavelier *et al.*, 2000; Levanen & Hamdorf, 2001). In children with normal hearing, synaptic density in the temporal cortex peaks at between 2 and 4 years of age, with HI resulting in delayed synaptogenesis in the auditory cortex (see Kral & Sharma, 2012 for a review). Auditory stimulation is required for normal development of speech perception and language during a “sensitive period” of higher neuronal plasticity up until the age of about 3.5 years. After the age of 7 years, irreversible changes in cortical organization prevent adequate processing of auditory signals. These findings are consistent with the evidence from congenitally deaf children with cochlear implants; early implantation is associated with good spoken language development whereas later implantation may enable the child to detect auditory stimuli but not discriminate complex sounds and only develop limited speech understanding and oral language (Kral & Sharma, 2012).

Hearing impairment and complexity

Assessment and diagnosis of neurodevelopmental disorders

Around 40% of children with HI have additional impairments arising from the underlying syndromic etiology including generalized or specific intellectual disability, visual impairment, autism, ADHD, motor, and health impairments. ASDs are

more common among HI than hearing children at around 2–4%, and the prevalence appears to be increasing (Szymanski *et al.*, 2012). Intellectual or learning disability, with its consequent impact on adaptive behavior, affects around 8–10% of children with HI, and specific learning disability a further 8% (<http://research.gallaudet.edu/Demographics/annsrsvy.php>; The Ear Foundation, 2012). Significant neurodevelopmental motor impairments, primarily as a result of cerebral palsy, affect around 14% of deaf children. Rates of attention disorder and hyperactivity are elevated in HI children compared with their hearing peers (Hindley & Kroll, 1998).

In young children with HI great care must be taken to distinguish between ASD and other social communication difficulties that may arise as a result of the impact of HI on language and (preverbal) communication; in the former, there is typically a lack of communicative intent and the presence of restrictive, repetitive and stereotyped patterns of behavior (Edwards & Crocker, 2008a). In the early years, it may be difficult to distinguish between these two forms of communication difficulties. It is common for very young children with HI to actively avoid eye contact or to show restrictive interests in certain toys or activities. While these may be early warning signs of ASD, for many deaf children they are more transient and may reduce with targeted intervention and as more adaptive function emerges. As language develops, these behaviors frequently disappear along with the concerns regarding ASD.

Appropriate diagnosis is most reliably made by multidisciplinary teams with expertise in HI. In children with sensory impairments, cerebral palsy, or other neurodevelopmental impairments, assessment is challenging. Motor or visual disabilities may “mask” relatively well-preserved intellectual abilities, with serious consequences for educational placements and expectations for achievement. Complexity is sometimes used to justify slow progress without identifying other factors, which also need management.

Psychological and psychiatric issues

There is little epidemiological consistency in the reported prevalence of mental health problems with prevalence rates ranging from 11% to 60%; this arises from differences in sampling, assessment method, definitions of “disorder” and criteria for clinical “caseness” (Hindley *et al.*, 1994; Cornes *et al.*, 2006). Further risk factors, such as low language competency, additional disabilities, severe learning difficulty, communication difficulties with family or peers, being bullied, isolation, discrimination, and child abuse, are likely to contribute to emotional and behavioral problems, all of which warrant exploration when assessing psychological or psychiatric disorders clinically (Fellinger *et al.*, 2009; Hogan *et al.*, 2011; van Gent *et al.*, 2011). The overall picture is a higher risk for psychological and psychiatric difficulties in children with HI, though there is considerable individual variation.

Parenting a child with HI is described by mothers as more stressful than parenting a hearing one (Horsch *et al.*, 1997).

However, research suggests that the stresses may vary over time and be related to factors such as behavior problems and language delays (Lederberg & Golbach, 2002; Quittner *et al.*, 2010). Mothers of young children with profound hearing losses have been reported to use physical disciplinary methods for behavioral transgressions more than mothers of hearing children (Knutson *et al.*, 2004).

One of the most common presentations to child mental health services of preschool-aged children with HI is severe noncompliance with adult requests, temper tantrums, and aggressive behavior. Parents typically report that they do not know how to set boundaries and feel helpless in conveying instructions or explanations when the child's language is significantly delayed. Parental attitudes toward childrearing, disability, and personal feelings of guilt or loss may contribute to expectations of the child's appropriate behavior and use of disciplinary strategies. Psychoeducation and behavioral interventions adapted to accommodate the child's communication and language level are effective if implemented in conjunction with support to improve parent-child communication.

School-aged children have an increased referral rate for assessment of ADHD. Delays in language acquisition and deficits in executive function may result in difficulties mastering affect regulation and verbally mediated self-control, with consequent behavioral manifestations of poor attention, impulsivity, and hyperactivity. The assessment and diagnosis of ADHD in children with HI is complicated and controversial; behaviors considered diagnostic in hearing children must be interpreted with caution in those with HI. For example, appearing not to listen when spoken to directly and being distracted by irrelevant visual stimuli are behaviors typical of children with HI; they may not be aware that they are being spoken to or are monitoring what is happening around them visually to compensate for the lack of auditory information (Edwards & Crocker, 2008b). Effective management of these difficulties can usually be achieved through psychoeducation of parents and teachers and behavioral strategies with infrequent necessity for pharmacological treatment.

Anxiety disorders such as obsessive compulsive disorder and social anxiety disorder tend to emerge in older children and adolescents with HI, similar to their hearing peers. High levels of anxiety may be associated with issues around the individual's developing identity and the perception of self as deaf or hearing and their involvement with Deaf culture. Depressive disorders occur more commonly in adolescence and need to be considered in the context of the individual's school setting (whether there is a comparable peer group), emerging personal identity and the ease of communication within the family in terms of communication mode (e.g., Fellinger *et al.*, 2009; Mance & Edwards, 2012).

Assessment and interventions need to take into account the child and family's views regarding communication and treatments such as CBT, family, narrative, or solution-focussed therapy will need to be tailored appropriately.

Professional approaches for management and care

The gold standard for the management of children with VI or HI (or dual sensory impairment) is a multidisciplinary care package, with an integrated service comprising health, education, and social services. The infant and preschool child with VI requires ophthalmology and a peripatetic teacher of the visually impaired and for those with HI the provision of audiology, speech and language therapy, and peripatetic teacher of the deaf. During the early years, the children need access to highly specialized multidisciplinary paediatric teams with expertise in VI or HI and neurodisability, including paediatricians, psychologists, speech and language therapists, occupational therapists, and other clinicians as required. Because of the vulnerabilities of the early years, intervention should promote general development and progress should be closely monitored and reviewed. School-age children continue to need input from the full range of services and on-going support from specialist teachers for VI or HI. Close monitoring of progress from all perspectives will need to continue, with occasional review by multidisciplinary specialist services as required (e.g., at times of education transition). Individualized family centred care, including working with parents in partnership, is known to be the most effective care model for supporting any family with a child with disability.

Assessment of cognition and language

Regular developmental assessments across infancy and preschool years are needed to monitor development and progress. The Reynell Zinkin Scales of Visual Handicap (Reynell & Zinkin, 1978) are the only semi-standardized developmental scales for VI infants (to 5 year olds) and have separate blind, partially sighted, and sighted norms. There is no equivalent for children with HI, although from 2 years of age the Leiter International Performance Scale-Revised is a useful assessment of non verbal reasoning, memory, and attention skills (Roid & Miller, 1997). Auditory/verbal tests and visual/non verbal cognitive tests can be used to assess the child's intellectual level of ability in VI and HI children respectively. Very few standardized tests of intelligence or neuropsychological processes have norms for VI or HI children; test results should, therefore, be interpreted cautiously. The Intelligence Tests for Visually Impaired Children-ITVIC (Dekker *et al.*, 1991) has Dutch norms for children with no or low vision and covers non verbal subtests including haptic and spatial discrimination, memory, and reasoning. Particular challenges occur for testing VI or HI children's language abilities when using standardized language tests, which are pictorial or oral linguistic respectively.

A minority of children with VI have specific difficulties in reading or "braille dyslexia," though the causes are debated (Dodd & Conn, 2000; Greaney & Reason, 2000). Dyslexia is particularly challenging to diagnose in the context of HI as it is difficult to distinguish from the typical or expected impact

of HI on the development of literacy skills and is probably under-identified (Edwards, 2010). No specific test of phonological awareness, reading, and spelling is reliable for testing HI children, but some are found to be clinically helpful in describing the difficulties experienced.

Psychological and psychiatric services

In all community and specialized services, holistic positive psychology approaches focussing on normalization, quality of life, self-determination and effective problem solving and coping abilities may assist young people and their families. These protective factors may enhance resilience and self-worth and help overcome the negative self-concept, stigma, and discrimination associated with disability (Wehmeyer, 2013). The richness and diversity of Blind culture and community, such as Blind Sports, and Deaf culture and community with the use of British Sign Language for communication need to be fully recognized.

Nevertheless, the clinician needs to be alert to the full range of possible psychopathology in children and young people with VI or HI, as in sighted peers. Formulation, diagnostic, and treatment approaches draw on the same principles as with a typical child of similar age and intellectual capacity, but need to be informed and tailored to needs arising from the VI or HI.

Access to psychological and psychiatric services comprising professionals with the expertise needed to work with children with VI or HI is still limited. A very small number of highly specialized paediatric services have integrated psychological input for children with VI or HI as part of the specialized developmental vision service or cochlear implant programme respectively. Only a minority of these services include psychologists. The large number of referrals to these services for assistance with behavioral and emotional difficulties highlights the clinical need for specialized provision for supporting children with sensory impairments and their families and educators.

In the absence of support or help from these services, young children may be attended by their local child development team and older children and adolescents may be referred to Child and Adolescent Mental Health Services (CAMHS). In recent years, a small number of specialist Deaf Child and Adolescent Mental Health Services (DCAMHS) have been developed to provide input to deaf children whose primary mode of communication is sign language. Wherever the child is treated, it is essential that their communication abilities and preferences are understood and accommodated, using sign language interpreters if required. Training in deaf awareness and knowledge of the cultural and developmental aspects of deafness are important for working with children with HI and their families. Training in awareness about VI, how to interact with and interpret the socio-emotional responses of the young person (e.g., lack of facial expression, eye contact, and other bodily communications) and knowledge of the developmental and psychological aspects of VI are important for working with children with VI and their families.

Management and intervention may be more complicated compared to those in typically developing children with emotional or behavioral disorders as the child with VI or HI is likely to have more professionals and services already involved in their care.

Global perspective

An estimated 19 million children are visually impaired worldwide. Of these, 12 million children are visually impaired due to refractive errors, a condition that could be easily diagnosed and corrected. Over one million children have an irreversible VI of which nearly a half of these could have been avoidable (Kong *et al.*, 2012). The prevalence of VI is related to the socio-economic status of the country, reaching 15 per 10,000 in low income countries, primarily due to diseases and risk factors (measles, vitamin A deficiency and malaria). A rising incidence of retinopathy of prematurity is occurring in middle income countries, such as Latin America and some eastern European countries, as more low weight premature babies survive and more specialized neonatal care is required. In the United Kingdom, children from some ethnic minorities, in particular Pakistani and Bangladeshi groups, are over represented among children with VI. The needs of ethnic minority families with children with VI are harder to establish because they are under represented in health research (Rahi *et al.*, 2005).

Sixty two million children worldwide under the age of 15 years are hearing impaired, with two thirds of those living in low- and middle income countries (Olusanya *et al.*, 2005) with poor health care and lack of prevention for infections such as rubella and meningitis. Limited or no access to hearing aids or cochlear implants, along with cultural beliefs, stigma, and discrimination, result in children failing to develop effective communication or language and thus their exclusion from family and society, with no prospect of employment. A significant number of children from immigrant families in the UK, USA, and other high income countries present to audiological services “late” with undiagnosed HI as a result of lack of screening in their country of origin. The delay in access to appropriate audiological care typically has an irreversible impact on long-term outcomes and the situation is frequently exacerbated by difficulty engaging families with health and educational services, which needs to be addressed as part of a package of care for the child and family.

CHAPTER 48

Assessment and treatment in nonspecialist community health care settings

Tami Kramer and M. Elena Garralda

Academic Unit of Child and Adolescent Psychiatry, Imperial College London, UK

Introduction

Nonspecialist community health-care settings, referred to as primary health-care services, are the first point of contact for families seeking professional attention for health problems. Primary care aims to clarify demand, diagnose disorder, offer information, advice, treatment, and rehabilitation as well as coordinate care with other disciplines and health sectors over time (Boerma, 2006). The place of primary health care in the management of mental health problems has long been recognized, as has the need to enhance its role and build capacity to help reduce the global burden of suffering and impairment caused by mental and behavioral disorders (WHO, 2005). Moreover, the primary care setting offers scope for prevention and early intervention for these disorders. Its role in the field of child and adolescent mental health (CAMH) has been comparatively little documented, but evidence for its potential is slowly accumulating.

This chapter outlines the different structures of nonspecialist community or primary health-care settings across countries, documenting presentations of children and young people with mental health problems in primary care settings and discussing their identification and management by primary care workers. It documents innovative models of mental health service delivery involving partnerships and coordinated care across different health sectors and considers the place of primary health care in the prevention of child mental health disorders. We refer to the setting under consideration predominantly as primary health care and will use the terms general or family practitioners/physicians interchangeably.

Generalist primary health settings

Primary health-care services vary widely across different countries in funding source, setting, staffing provision relative to

the size of the population, and support from specialist services. Services are delivered by a range of physicians, usually general practitioners or family physicians, and/or general and community pediatricians as well as nonphysician health workers, often nurses, health visitors, or public health workers. European pediatric primary care is medically delivered by family practitioners (41%), pediatricians (24%), or a combination of the two (35%), although there has been a recent decline in the number of primary care pediatricians (van Esso *et al.*, 2010). Conversely, in the United States where pediatricians, family physicians, and nurse practitioners provide pediatric primary care, over the last three decades provision by pediatricians has increased (Freed *et al.*, 2010), while in Canada pediatric primary care is provided largely by general practitioners and public health units.

Family practitioners and pediatricians provide different patterns of preventative and curative care (Freed *et al.*, 2004). Family practitioners tend to become involved in prevention and management of physical health problems especially of young children, whereas primary care pediatricians have a broader remit, encompassing the prevention and community management of physical problems, assessing growth and development, child protection, school medicine, behavior problems, and teenage health. It is worth noting, however, that only 40% of countries have community pediatricians and consequently the type and quality of primary care for child mental health problems varies considerably (Katz *et al.*, 2002).

In many low and middle income countries (LMICs), the point of first contact with health services is public health workers, whereas pediatricians provide specialized Western-type medical care (Cheng, 2004). Lay and community or village health workers are trained to offer selected clinical and preventive services as part of “*task shifting*,” the practice of delegating tasks to workers with lesser professional and nonprofessional training in order to increase capacity (Bruckner *et al.*, 2011; Fulton *et al.*, 2011). Primary and secondary health care delivery for children in

LMICs may also include primary care clinics or health centers, child clinics, school medical services, emergency departments, and ambulatory hospital/outpatient departments. As in higher income countries, funding may be private, insurance based, or part of centrally organized national or regional health services.

In addition to the wide array of different service structures and personnel the level of training given to primary care workers in child and mental health has an impact on provision. Training, however, is quite limited overall. Mean length of specialist pediatric training for family doctors in Europe is 4 months and some have none (van Esso *et al.*, 2010): training in child mental health is even less prevalent. The WHO Child Mental Health Atlas (2005) reported that in only 15% of countries had at least a quarter of their pediatricians received mental health training.

Core roles of primary health care for child and adolescent mental health

As primary care services generally provide the most widespread initial point of contact for health services, they are ideally placed for a role in mental health promotion, prevention, and early intervention. They are also in an ideal position to clarify concerns, signpost help, and refer more severe and complex cases to specialist services. At the same time, they are able to directly offer advice and intervention for milder problems through psycho education and supportive counseling, parenting support, psychotropic medication, and brief cognitive/behavior therapy (see Box 48.1). For children with chronic conditions primary health care has an on going role in monitoring, supporting and coordinating interventions with secondary and tertiary health services, social services, education, and nongovernmental organizations.

The particular scope of the role of primary health care will be determined by local factors and health provision should be shaped accordingly. Disparities in specialist child psychiatric and mental health services are wide, with a higher concentration of services in urban and affluent areas (Morris *et al.*, 2011); poorer and more rural communities frequently having little or no access and being therefore more reliant on primary care. A European survey found that the populations covered by child psychiatrists ranged from 5300 to 52,000 individuals (Remschmidt & van Engeland, 1999). In most countries in Africa, the Eastern Mediterranean, Southeast Asia, and Western Pacific, this range is much broader, of the order of 1 to 4 child psychiatrists per million population. Within countries with

well-developed specialist mental health services, there is an opportunity for primary care to act as a referral gateway to mental health specialists. Where these services are scarce, primary care will act more as a direct source of care with specialists' efforts focussing on supporting primary care providers.

No country has documented fully meeting the need for child and adolescent mental health services (CAMHS) (WHO, 2005). Over the years, this worldwide deficit in provision has resulted in calls to develop the role of primary health care as a means of helping bridge the gap. Primary care has unique strengths as it offers broad direct access, reduced stigma, continuity over time, and knowledge about situations that put children at risk for psychiatric disorders such as families with parental mental illness or substance misuse. Despite this, implementation of programs to increase primary care capacity has been slow. Across most countries, less than 10% of CAMHS are provided by primary care (WHO, 2005).

Child and adolescent mental health problems in nonspecialist primary care settings

Frequency of contact with primary health care

Contact with primary health care is a common experience in childhood and adolescence. Over the course of 1 year, most parents take their children to primary health care services, and work with children has been estimated to occupy a significant proportion of primary care consultations (18% with under 15 year olds in the United Kingdom, 17% in the United States, and 12% in Australia) (Freed *et al.*, 2004; Britt *et al.*, 2008; RCGP, 2008). There are age trends with young preschool children being seen more often than older children, but even so surveys, mainly from high income countries, estimate that as many as 70–90% of young people are in contact with primary care services at least once a year (Tylee *et al.*, 2007), offering a significant potential for intervention.

Modes of presentation

Children and young people present to primary health care for acute complaints as well as health surveillance. The majority of consultations relate primarily to physical concerns. Surveys in various countries have documented that only 1–6% of children and adolescents attending primary care or general pediatric clinics present with primary psychological, behavioral, social, or educational problems (Garralda & Bailey, 1986, 1989; Kramer & Garralda, 1998; Eapen *et al.*, 2004), though other countries

Prevention of psychiatric disorder and developmental disability
First point of contact for concerns
Clarification of concerns

Early intervention
Brief interventions for less severe and complex conditions
Support and care coordination for chronic conditions

report higher rates of up to 10% (Haller *et al.*, 2007; Hetlevik *et al.*, 2010). One large survey in the United States demonstrated that 1% of emergency department visits concerned primary mental health presentations and, of those, patients with mood disorders and psychosis were most likely to present more than once.

Other points of contact

Moreover, broad access to children and young people within school provides opportunities for primary health intervention including attention to emotional and behavioral well-being, risk reduction, resilience building, mental health promotion, and access to help for mental health disorders, thus complementing primary health care provision (Table 48.1) (see Chapter 42).

Identification of mental health problems in primary care

Frequency and nature of psychiatric disorder in attenders

There is evidence that psychiatric disorders are present in a considerably higher number of children attending primary health care than may be expected from the overt presenting complaint or from expected disorder rates in the population (Ford *et al.*, 2007). Research interviews with children and parents, following primary care contact, have found psychiatric disorders in one-tenth to one-quarter of children across different countries (Garraalda & Bailey, 1986; Costello *et al.*, 1988; Gureje *et al.*, 1994; Eapen *et al.*, 2004), with higher rates in adolescents (40%), (Kramer & Garraalda, 1998), schoolchildren attending hospital pediatric outpatients (28%) (Garraalda & Bailey, 1989), and children and young people who are frequent service attenders (29% in 7–12 year olds) (Bowman & Garraalda, 1993; Vila *et al.*, 2012).

Although the range of psychiatric disorders are represented emotional disorders predominate (Garraalda & Bailey, 1986; Kramer & Garraalda, 1998), with mild to moderate Diagnostic and Statistical Manual of Mental Disorders (DSM). DSM-IV

defined anxiety disorders in a third of attenders (Burns *et al.*, 1995; Leaf *et al.*, 1996; Chavira *et al.*, 2004). It is likely that the psychiatric disorder contributes to consultations because of the poorer physical well-being of children with emotional disorders and high levels of parental stress about these children (Kramer & Garraalda, 1998; Garraalda *et al.*, 1999). Mainly, psychiatric symptoms are not mentioned during consultations and go unrecognized.

In the United Kingdom, elevated levels of persistent depressive symptoms (both subsyndromal and diagnosable depressive disorders) have been detected in adolescents attending general practice in both urban and suburban areas reinforcing the relevance of primary care for adolescent depression across socioeconomic groups (Yates *et al.*, 2004; Gledhill & Garraalda, 2011, 2013). Depressive symptoms in adolescents attending primary care are associated with increased risk of substance abuse and school problems (Yates *et al.*, 2004; Burns *et al.*, 2004). This and high levels of depressive disorder in young people attending other community health settings, such as sexual health clinics (Fernandez *et al.*, 2009), suggest that identifying psychopathology within primary care will provide the opportunity to address a wide range of psychosocial difficulties.

Within LMICs, however, neuro-psychiatric problems, such as those associated with epilepsy, may be more prominent within clinic-attending populations in line with the increased population levels of brain damage and severe intellectual disability (Patel *et al.*, 2008).

Recognizing need and diagnosing disorder

Attention to mental health problems in primary care is only possible once the problems, their nature, and severity are recognized and any demand for intervention clarified. As a first step, recognition requires either an expression of need by the parent or young person or spontaneous enquiry by the practitioner. However, although parental expression of concern increases clinician recognition (Sayal & Taylor, 2004), and even though many parents believe that it is appropriate to express difficulties with child

Table 48.1 Relative merits of primary health care versus school interventions for mental health problems.

Primary health care	School
Nonstigmatizing	Nonstigmatizing
Confidential	Uncertain confidentiality
Access to most children and young people including school nonattenders	Access to many children and young people
Identification of difficulties dependent on patient expression of concern	Behavioral concerns identified more frequently than emotional difficulties
Practitioners often know family circumstances	Knowledge of family limited
Some doctors specifically trained	Some teachers trained in special needs
Training needs in screening, intervention and referral	Training needs in screening, class management and referral
Setting suitable for individual brief consultations	Setting requires adaptation for individual consultation

behavior to a primary care provider, few with such concerns do so (Horwitz *et al.*, 1998; Ellingson *et al.*, 2004; Sayal & Taylor, 2004). For children under 4 years old, Ellingson *et al.* (2004) demonstrated that whether parents discuss the child's problems was linked to parental worry, perceived low socio-emotional competence in the child, and disruption to family routines.

As children enter adolescence their own readiness to raise concerns is important. Nevertheless, even when adolescents perceive themselves to have serious difficulties, half fail to mention them during the consultation; conversely, practitioners fail to discuss psychological issues even when they perceive them to be present (Martinez *et al.*, 2006). Sayal's (2006) systematic review documented low rates of recognition of both psychiatric disorder and broader psychosocial concerns, with recognition low in sensitivity (15–20% for psychiatric disorder and 50–57% for psychosocial difficulties) but high specificity (84–96%). The higher sensitivity for recognition of psychosocial difficulties over psychiatric disorder might reflect either practitioner's greater awareness of psychosocial problems or their reluctance to use psychiatric diagnostic labels (Iliffe *et al.*, 2008).

Determinants of parental and youth help-seeking

Broad socio-cultural attitudes and values have an impact on decisions to seek help for mental health across population groups. Sayal *et al.*'s (2010) UK qualitative study classified barriers to parental help-seeking for child mental health concerns into parental perceptions of service features (such as difficulty getting appointments and short appointments), fear of the consequences of identification—for example, embarrassment, stigma, and labeling—and being judged a bad parent. The study also identified trust in the service and continuity of care as facilitators of parental help-seeking.

From the perspective of young people themselves, barriers to seeking help include a perceived lack of youth friendly services, stigma, and embarrassment, lack of mental health literacy, a belief that treatment will not help, and a preference for self-reliance (Rickwood *et al.*, 2007; Tylee *et al.*, 2007; Vanheusden *et al.*, 2008; Gulliver *et al.*, 2010). The facilitators of youth help-seeking are less well researched, but include positive past experiences, social support, and encouragement from others, as well as perceptions that doctors are interested in psychosocial issues (Ferrin *et al.*, 2009; Gulliver *et al.*, 2010).

Determinants of practitioner recognition

Practitioner recognition of mental health problems during consultations has been linked to a wide range of factors. These include (i) disorder-related issues such as severity and type of presenting physical symptoms—severe and chronic problems, digestive and ill-defined presentations being more likely to lead to identification of psychiatric morbidity; (ii) socio-demographic, with better recognition in males, 7–14 year olds over younger children, and in the presence of social difficulties such as socioeconomic disadvantage, broken homes, adverse life events, and academic problems; (iii) type of

consultation: well child clinics faring better than acute care visits; and (iv) a variety of other factors, such as the clinician's relationship with the child, parental and young persons' perception of difficulty, young persons' fears, impairment, and previous treatment for psychological problems (Goldberg *et al.*, 1984; Kramer & Garralda, 1998; Brugman *et al.*, 2001; Haller *et al.*, 2009).

Cultural factors and ethnic minority status might also affect recognition. In a Dutch study of well child visits by Crone *et al.* (2010), identification of psychosocial problems by clinicians was lower in children of Turkish and Moroccan descent compared with those of Dutch background.

However, overall, the best predictor of a primary care clinician (PCC) identifying a child's mental health problem is whether parents draw the clinician's attention to them rather than any clinician-initiated procedure (Zuckerbrot *et al.*, 2007).

It follows that important first steps in promoting primary care identification of child mental health problems should consider public education aimed at diminishing stigma and identifying primary care as a source of help, thus enabling parents and adolescents to identify needs and express them during the consultation. These expressions of concern by parents and adolescents will need to be met with practitioner understanding, empathy, and appropriate interventions, informed by adequate knowledge of normal development, emotional and behavioral problems, and evidence-based treatments. Primary care services will need to enhance capacity and interest in the field, and this will only be possible when clinicians feel confident to do so (Sanci *et al.*, 2010).

Systematic screening or case-finding

Use of screening or case finding instruments such as questionnaires has been considered a potentially quick and easy method to improve primary care identification of emotional and behavioral difficulty. Instruments should be brief; easy to administer, score and interpret; have adequate reliability and validity; identify a significant proportion of those with problems; and provide developmentally appropriate and clinically useful information. Case identification should lead to interventions which improve prognosis.

Primary care studies on questionnaires targeting emotional and behavioral symptoms demonstrate reasonable sensitivity, specificity and feasibility across the age range (Zuckerbrot *et al.*, 2007; US Preventive Services Task Force, 2009) as does the alternative approach of brief systematic clinical questioning by clinicians (Rutman *et al.*, 2008; Wintersteen, 2010). However, the implementation of screening programs such as the American Medical Association's Guideline for Adolescent Preventive Screening has had mixed results, and increased screening is also likely to enhance the need for specialist CAMHS (Elster & Kuznets, 1994; Ozer *et al.*, 2009).

Electronic screening

One means of facilitating primary care mental health screening is use of computer or internet-based tools by young people

waiting to see the primary care practitioner (PCP) (Stevens *et al.*, 2008; Fein *et al.*, 2010) but further work is required on practical implementation, including the process for feeding results to practitioners and how information is used within the consultation.

At best, however, screening questionnaires or systematic screening questions provide a guide for further enquiry. Importantly, evidence on whether they lead to improved access to effective intervention or to better health outcomes is lacking. Moreover, this depends on whether identified adolescents feel “ready” to accept intervention (Tanielian *et al.*, 2009) and this “readiness” is likely to be linked to cultural factors (Brown *et al.*, 2007). The adult literature shows that screening or case finding for adult depression in primary care shows little or no impact on recognition, management, or outcome of depression (Gilbody *et al.*, 2005), unless this is embedded within a broader program of collaborative care (Gilbody *et al.*, 2006).

Delivering interventions, partnerships, and coordinated care

It is clear that policies aiming to reduce the service gap in meeting the mental health needs of children and young people through improved access to interventions within primary care will only be realized through substantial expansion of primary care provision. Unfortunately, there is a dearth of quality intervention research (Martinez-Castaldi *et al.*, 2008). Nevertheless, descriptions of innovative collaborative approaches have begun to accumulate. They include a focus on complex interventions for specific disorders, broad restructuring of service design and delivery, and incorporation of the collaborative approach found to be effective in the adult population. These approaches will now be summarized following a description of the more traditional models.

Traditional models of service design and delivery

A systematic review of child mental health interventions offered within primary care in the UK (Bower *et al.*, 2001) identified three different types of services: (i) management by specialist mental health professionals in primary care, often referred to as shifted outpatient clinics; (ii) treatments offered by the primary care team; and (iii) consultation liaison models. The review identified few quality studies to support these approaches and highlighted the need for research.

Specialist or shifted mental health clinics

Early work on treatment by specialist staff within primary care included brief interventions (6–12 sessions) and a variety of techniques such as psychiatric evaluation and guidance, nondirective counseling, parent education and counseling, cognitive behavior and family therapies, dynamic therapy, group work, and child education (Bower *et al.*, 2001). More recent evaluations of outreach psychologist, therapy or nurse primary care

clinics have yielded mixed results (Day & Davis, 2006; Kolko *et al.*, 2010).

Despite this, in the US “colocation” of mental health specialists within primary care facilities is advocated as a means of improving mental health service utilization through diminishing stigma, while at the same time increasing care coordination and educational exchanges between primary care and specialist practitioners (Williams *et al.*, 2006). Comprehensive coverage of primary care settings of this kind would, however, require high numbers of mental health specialists and is probably not achievable in most regions of the world.

Treatments offered by the primary care team

There has been limited study of the management of child emotional and behavioral difficulties offered by the actual primary care team. Although early work by one general practitioner using preventative interviews with preschool children demonstrated significant improvement in some child outcomes (Cullen, 1976), widespread primary care management of mood or anxiety syndromes (Wren *et al.*, 2005) or attention deficit hyperactivity disorder (ADHD) (Sonuga-Barke *et al.*, 2004) would appear to be uncommon and ineffective. Thus, the impact of the work of PCCs themselves within traditional models of service delivery remains relatively untested and recent work has focused on more complex and collaborative models of care (Table 48.2).

Consultation-liaison

Consultation-liaison, where the specialist acts to support primary care management rather than take responsibility for individual patients (Gask *et al.*, 1997) has traditionally been viewed as a means of increasing the capacity of PCCs to offer mental health services, partly through improving their skills and knowledge.

Table 48.2 Child & adolescent psychiatric problems appropriate for direct primary health care intervention.

Nature of problems	Childhood disruptive behavior disorders (including ADHD) Somatization Anxiety disorders Depressive disorders Adjustment disorders
Severity of problems	Mild-moderate impairment Low complexity (e.g., no co morbidity, low family risk)
Treatment needs	Psycho education Self-help Parenting support/intervention Medication Brief psychotherapy

CAMHS work in this area has been little documented or evaluated (Neiro-Munoz & Ward, 1998). In a model by Connor *et al.* (2006), a child psychiatrist or specialist nurse offered telephone consultation during office hours to 139 PCP's. A proportion of cases were then managed within primary care while the rest were referred to the child psychiatrist for assessment within 4 weeks. During the first 18 months, the child psychiatrist offered direct evaluation to half the patients. Time was also spent educating PCP's in case conferences and informal consultations. This model served as a pilot for developing a more complex intervention, the Massachusetts Child Psychiatry Access Project (MCPAP), described later.

In the UK, a survey of all specialist CAMHS in England demonstrated that collaborative work with primary care was significantly associated with well developed 'specialist' provision, and larger sized services (Bradley *et al.*, 2003). This confirms the difficulty for small specialist CAMHS to provide consultation liaison in primary care. Furthermore, future work will need to address the medico legal responsibilities in those cases where PCP's with limited training and experience in the area provide treatment on the advice of specialist clinicians, especially when prescribing psychotropic medications.

Newer models of collaborative care **Disorder specific models**

Collaborative care differs from the traditional models described earlier as it is a complex, multifaceted, organizational intervention involving combinations of staff working in new ways, with varied content and intensity (Bower *et al.*, 2006). These programs include the flexible use of consultants, care managers as patient educators, and mental health clinicians working with PCCs. This model has shown effectiveness for adults with depression and anxiety, especially when they have access to an adult psychiatrist.

Adolescent depressive disorders

The use of the collaborative care model in child mental health has been best addressed in adolescent depression. Asarnow *et al.*'s (2005) quality improvement study (Youth Partners in Care) was the first multisite effectiveness trial for depressed adolescents in primary care. It demonstrated superiority over usual care in reducing depressive symptoms, and increasing both quality of life and satisfaction with care at 6-months posttreatment. The intervention included: (i) expert leader teams at each site; (ii) care managers to support PCCs with evaluation, education, medication and psychosocial treatment, and with linking to specialist mental health services; (iii) training care managers in manualized cognitive behavior therapy (CBT); and (iv) access to participant and clinician choice of treatment. Treatment options included CBT, medication, combined CBT with medication, care manager follow-up, and specialist referral. At 12 and 18 month follow-up, there was a trend for between-group differences, although these were not statistically significant (Asarnow *et al.*, 2009). The sample size in this study was smaller than that in adult studies and

larger samples might be required to demonstrate significant differences.

Of note, the majority of youth in either treatment arm failed to take up any intervention, indicating that universal treatment coverage was far from achieved, and for those that did there were higher rates of uptake for psychotherapy. In light of the known efficacy of medication and combined treatments for adolescent depression (March *et al.*, 2004; Brent *et al.*, 2008), these findings suggest that additional attention to health beliefs and treatment-readiness might be required as part of psycho education.

Within the UK, the TIDY program or Therapeutic Identification of Depression in Young people (Kramer *et al.*, 2012) has been developed incorporating specific training for PCPs. The target is screening and identifying depression, followed by primary care delivered interventions for mild and moderate cases based on cognitive and interpersonal principles. TIDY has been shown to be feasible and acceptable to practitioners (Iliffe *et al.*, 2012; Kramer *et al.*, 2013). Implementation leads to significantly improved rates of depression recognition and provides practitioners with clear guidance on which young people require specialist referral. As this model is less resource intensive than others described earlier it may prove adaptable for lower resource environments. Moreover, it is appropriate for use in subthreshold depression, which is common and persistent among young people in this setting (Gledhill & Garraida, 2013).

Early behavior disorders

Evidence is accumulating on the use of collaborative interventions within primary care for early behavior disorders. Kolko *et al.* (2012) enhanced their program of colocated nurse provision, with a doctor-led intervention incorporating psychoeducation, parent and child skills training, and ADHD management alongside mental health practitioner delivered psychoeducation compared to enhanced usual care. This intervention was significantly superior in service use and completion, and improved child behaviors and was associated with high pediatrician and parent satisfaction.

Usual care in this study was substantial and it might be argued that the intervention was a specialized package delivered within the primary care setting, therefore not feasible in lower resource settings. The challenge lies in replication with nonspecialist health workers or with lay workers picking up specific tasks as in *task shifting* and as trialed in India with adults (Patel *et al.*, 2010).

However, less complex individual and group parenting interventions, have shown effectiveness when delivered in primary care (Stewart-Brown *et al.*, 2004; Turner & Sanders, 2006; Lavigne *et al.*, 2008), even when delivered by nonspecialist trainers within the voluntary sector (Gardner *et al.*, 2006) and using trained peer facilitators (Day *et al.*, 2012). Manualized self-help programs (Lavigne *et al.*, 2008) and those with telephone support (Reid *et al.*, 2013) have shown similar effectiveness.

Given the success of community-based group parenting programs (see Chapter 37), it would appear appropriate for primary

care to have a role in the initial detection and referral of behavioral problems. Thus early treatment of behavior disorders following a stepped approach that starts with self-help and moves onto peer or professionally delivered programs in primary care and to specialist referral for the most complex cases would use resources effectively.

Attention deficit hyperactivity disorder (ADHD)

This stepped care approach is also appropriate for ADHD (Leslie *et al.*, 2004) and may be supplemented with internet resources (Epstein *et al.*, 2011), although it requires specific training for clinicians, as well as resources within primary care for liaison with schools and mental health agencies (Power *et al.*, 2008). Current programs have involved US primary care pediatricians and it is unclear whether medical practitioners in other countries would participate to the same extent.

Broad service redesign and delivery models

Innovative programs that involve change in service design and delivery for the range of child psychiatric problems have been described across a range of countries, predominantly those with higher incomes. They include (i) collaborative care services which incorporate a combination of consultation, coordination and education for primary care providers, and (ii) integrated youth services, combining a broad range of cross-sector provisions incorporating general and mental health, education, or vocational services and social care.

Collaborative care services

Campo *et al.* (2005) described a US collaborative care service illustrating the stepped care approach. The team included an advanced practice nurse located within primary care who performed the initial assessment, triage and psycho education, as well as medication management and brief psychotherapeutic interventions; a social worker who delivered on-site psychotherapy; and a child psychiatrist attending weekly sessions for case reviews, supervision, consultation, and to attend selected children.

Other US collaborative services have been developed (Gabel, 2010; Sarvet *et al.*, 2010; Gabel & Sarvet, 2011; Hilt *et al.*, 2013). PCPs who are central to this approach receive mental health assessment and treatment training. Individual consultation by child and adolescent psychiatrists is provided mainly by telephone but also face-to-face and via video-conferencing with support regarding referral. Similar innovations have been described in other countries, for example, in Finland (Laukkanen *et al.*, 2010) and through the development of primary care child mental health workers in the UK (Macdonald *et al.*, 2004; Hickey *et al.*, 2010).

The MCPAP is the most established of the collaborative care programs. It comprises six regional teams each including a child psychiatrist, a child and family psychotherapist, a care coordinator and, in some teams, an advanced practice registered nurse who works in a role similar to that of the child psychiatrist

(Sarvet *et al.*, 2010). The service is accessed via a telephone hotline and the call is routed to the most relevant MCPAP team member. Over 3 years 353 practices (1341 PCPs) enrolled covering 1.36 million children. A provider survey demonstrated that more felt that they are able to meet patient emotional or behavioral needs (increased from 8% to 63%), more felt that they had received a timely consultation (from 8% to 80%), and perceptions of adequate access to a child psychiatrist rose from 5% to 33%. Similarly, the Partnership Access Line (PAL), in Washington State involves a large rural population with poor access to child psychiatrists (Hilt *et al.*, 2013).

Integrated youth service models

Integrated youth services have been advocated as a means of improving young people's access to and engagement with mental health services. (Tylee *et al.*, 2007; Anderson & Lowen, 2010). Services of this nature include Headspace in Australia with a focus on "youth friendliness" by being accessible; comprehensive, including both physical and mental health provision, and colocated with youth workers, and other social and vocational services (Patulny *et al.*, 2013). However, evidence on efficacy so far is limited to case descriptions and uncontrolled observational studies.

Prevention and early intervention

The widespread, comprehensive, and community-based nature of primary care services, their knowledge of local social and family risk factors for CAMH and well-being puts them in a unique position to contribute to prevention and early intervention and help prevent the development of chronic conditions. However, questions arise about whether preventative programs are best delivered within clinical or community settings and whether they should be universal or selective. Complex research designs with long follow-up are required to demonstrate impacts on health outcomes, harms, and cost-effectiveness (Sanci, 2011) (Box 48.2). (Cross reference Prevention of Mental Disorders and Promotion of Competence—Chapter 17).

Primary prevention

By targeting risk and resilience factors both well care and acute visits present opportunities for primary prevention in children and young people. Examples include family planning programs, pre- and postnatal care including detection and management of maternal depression, promotion of adequate nutrition, information on child safety, and home visiting programs. A range of professionals including general/family practitioners, primary care pediatricians, community pediatricians, advanced practice nurses, health visitors, and community nurses are all in an excellent position to disseminate information on child health, development, behavior, and positive parenting (Bower *et al.*, 2003; Van Cleve *et al.*, 2013).

Parenting programs

Iodine and iron deficiency prevention

Early intervention

Parenting programs for early behavior problems
 Adolescent health risk screening, counseling, and psycho education

A study of preventative consultations by one general practitioner aimed to influence parenting during the child's first 4 years; it demonstrated favorable outcomes on behavior at 6-years and even 20-years later (Cullen, 1976; Cullen & Cullen, 1996). However, it is unlikely that many general practitioners or pediatricians are in a position to invest the time required for such interventions. It may be more practical and cost-effective to implement prenatal and infancy home visiting by trained nurses with mothers at high risk of difficulties.

The best researched of home visiting programs for disadvantaged mothers (Olds *et al.*, 1997, 2007) have demonstrated benefits for young, low income, unmarried mothers, and their children in several large randomized controlled trials. (Cross reference Prevention of Mental Disorders and Promotion of Competence—Chapter 17).

By contrast, a far less intensive intervention in Iran—a randomized trial of a parenting intervention to prevent abuse—offering two sessions to mothers attending child monitoring visits in primary care—demonstrated significant change in maternal reported parenting practices (Oveisi *et al.*, 2010). It remains important to establish which elements of such interventions are the minimum required to achieve mental health gains for children.

Within LMICs links have been described between the early cognitive deficits associated with early stunting and living in poverty and impaired academic achievement, a possible mediator of the intergenerational transmission of poverty (Grantham-McGregor *et al.*, 2007). While primary care has a role in early detection of epilepsy and developmental delays, in order to prevent cognitive deficits, Walker *et al.* (2007) encouraged reduction of exposure to four key risk factors: under nutrition, inadequate cognitive stimulation, iodine deficiency, and iron deficiency. They concluded that there is sufficient evidence to warrant interventions for malaria, intrauterine growth restriction, maternal depression, exposure to violence, and exposure to heavy metals as a means of reducing cognitive deficits in children.

Outcomes of programs targeting child development have been mixed (Kieling *et al.*, 2011). A Jamaican trial of psycho-stimulation for stunted children was associated with significantly reduced anxiety, depression, and attention deficits, and enhanced self-esteem at age 17–18, when compared with dietary supplementation (Walker *et al.*, 2006). However, though commonly used, overall there has been so far little evidence of

effectiveness of skill training parents in enrichment activities for children with intellectual disability (Kieling *et al.*, 2011). Factors associated with effectiveness of early psycho-stimulation programs across LMICs include: providing services directly to children and skill demonstrations and practice with parent. Disadvantaged, stunted children benefit more than advantaged children, 2–3 year olds fare better than 5–6 year olds and longer exposure results in larger effects (Engle *et al.*, 2007).

As primary care may be the only service that many children access, particularly those under age 3, and in light of the close relationships between physical and mental health and development, the primary setting is well placed to provide preventative interventions. Nevertheless broad implementation to date has been slow (Engle *et al.*, 2007).

Early identification of behavioral problems and suicidal risk in adolescents

In adolescence much morbidity and mortality is associated with risk factors considered preventable and linked with mental health, such as substance use, risky sexual behavior, accidents, and suicide. Accordingly, preventative screening for health risks during primary care wellness visits by adolescents has been advocated as a means of detection and early intervention. Two trials including behavioral counseling for areas of concern identified through screening demonstrated modest effects on behavior (Walker *et al.*, 2002; Ozer *et al.*, 2011). Of note in one study identifying “possible” adolescent depression was associated with significant improvement in mental health scores at 3-months and 1-year follow-up (Walker *et al.*, 2002).

The role of primary care in suicide prevention has been well described (Gould *et al.*, 2003; Mann *et al.*, 2005). Many suicidal young people in the age range 15–34 years have contact with primary care in the month prior to suicide or self-harm (Pfaff *et al.*, 1999; Luoma *et al.*, 2002) and screening for suicidal thoughts has been found to be safe (Gould *et al.*, 2005) and have acceptable sensitivity and specificity (Shaffer *et al.*, 2004). Nevertheless, a US study of pediatricians and family physicians revealed that less than half reported that they routinely screened their adolescent patients for suicide risk (Frankenfield *et al.*, 2000). One-day training for general practitioners in Australia enhanced detection rates of distress and suicidal ideation, but failed to lead to changes in management (Pfaff *et al.*, 2001).

A trial of a computerized screening tool of primary care attenders demonstrated that young people are willing to disclose

suicidal thoughts using a computer screen within primary care and that a vulnerable group can be identified and managed (Gardner *et al.*, 2010) within a collaborative system of care.

Building capacity in the front line

Calls to increase primary care capacity to address CAMH are numerous; however, there are few comprehensive national policies or plans. Explicit in such proposals is the prominent need for training, including under- and postgraduate training, and continuing professional development. Dedicated training for pediatricians and general practitioners has been shown to lead to significant self-reported improvements in knowledge, skills, and confidence (Laraque *et al.*, 2009; Kramer *et al.*, 2013).

Exploring the barriers to work in this area has shown that general practitioners spend less time in consultations with young people than adults (Jacobson *et al.*, 1994) and that they have concerns about managing mental health problems within their time constraints (Iliffe *et al.*, 2012). They perceive young people as using primary care impulsively and intermittently, not engaging and being hard to communicate with (Iliffe *et al.*, 2008). They are wary of over-medicalization (Iliffe *et al.*, 2004), and using the word “depression,” although they feel more comfortable discussing “social difficulties” (Iliffe *et al.*, 2012). This indicates that training should address attitudinal factors in addition to practical skills. Excellent interpersonal communication skills are required to fulfill the central role of the PCC in overcoming barriers to help-seeking for mental health problems. Chronic care principles have been identified as relevant. A comprehensive toolkit has been developed as part of the Mental Health Gap Intervention Guide (World Health Organization, 2010).

Conclusions and further developments

Child psychiatric disorders are common among children and young people attending primary care, particularly among frequent attenders, although presentations are usually with physical symptoms and the psychiatric problems often go unrecognized. Nevertheless, because of its very nature the primary care setting provides a unique opportunity to help close the gap in service provision for children and adolescents with mental health problems. Initiatives to increase screening and attend to affected children and young people are slowly being described and piloted in primary care.

Future work should address the best use of screening during clinical consultations, consider the adjunctive use of computer or internet-based interventions, explore what contributes to patient readiness for treatment uptake following identification, and the potential harm of false positive identification. Controlled studies with adequate sample sizes are needed to ascertain whether systematic early detection in primary care

leads to better child mental health outcomes in the medium to long term.

Outstanding tasks to be addressed are public education to help diminish stigma and promote primary care as a source of help, helping clinicians facilitate parents’ and young people’s communication of their concerns during primary care consultations and generally building primary care professional capacity for CAMH.

New collaborative service models to help improve primary care involvement with CAMH need to be tested and piloted beyond their “product champions” and their efficacy rigorously demonstrated in terms of patient outcomes, but also in relation to service access, engagement, satisfaction, and cost.

Central to all these developments is an overall need, likely to be more pronounced in LMICs, to design and evaluate training programs for all frontline workers, whether general health practitioners, child care or education providers, or lay workers in CAMH.

CHAPTER 49

Forensic psychiatry

Susan Young¹ and Richard Church²

¹Centre for Mental Health, Imperial College London, UK

²South London and Maudsley NHS Foundation Trust, London, UK

Introduction

Forensic psychiatry is predominantly associated with children's interactions with the criminal and civil law—the assessment and management of mentally disordered offenders, or those at risk of offending, and issues such as mental competency, fitness to testify, reliability of testimony, victimization, and child custody disputes.

This is a complicated area, which may require clinicians to interact with the courts and consider legal aspects of a child's behavior. Typically, forensic psychiatry involves the assessment and management of both clinical and criminogenic factors presenting in mentally disordered offenders. A prominent aspect is the assessment and management of risks toward others, especially violence and other antisocial behavior—whether the individual has actually broken the law or not. Some aspects of forensic psychiatry are described elsewhere in this volume, including the chapters on intellectual disability, children's testimony and child maltreatment.

While there is considerable international variation in the development of adult forensic psychiatric services, there is even greater heterogeneity in forensic child and adolescent psychiatric services, both between countries and within regions of countries. Marked differences exist in the types of services delivered and the degree to which these services are integrated with other judicial or welfare agencies for young people. International standards are clear that whenever juveniles are deprived of their liberty, this should be as a last resort and always within an age-appropriate environment suited to their needs (United Nations, 1990). In this context, there is a requirement for specialized secure psychiatric services for mentally disordered young people who pose very high risks to others (Bailey *et al.*, 1994). In the absence of such specialist resources, mentally unwell young people are often kept in suboptimal

settings such as juvenile prisons, secure residential placements, secure mental health wards for adults and potentially fail to receive appropriate treatment.

Aside from secure psychiatric hospitals, forensic child and adolescent mental health teams may also be located in any setting where children are deprived of their liberty. Such teams may have significant roles in running specialized mental health services within institutions, assessing and managing risk and managing continuity in mental health care between the locked institution and other settings including the community. Similar teams work with juvenile offenders serving non custodial sentences in the community and may be linked to primary care services (Callaghan *et al.*, 2003). Such community-based teams typically liaise with a large number of partner agencies and may become involved in the assessment and management of young people who are not necessarily in conflict with the law, but who nonetheless present high risks to themselves or others (Table 49.1).

Juvenile justice systems: a global perspective

General principles of juvenile justice

The United Nations has published extensively on matters related to youth justice. Core principles are enshrined in the United Nations Convention on the Rights of the Child (United Nations, 1990), where Article 37 describes minimum standards in the treatment and punishment of juvenile offenders. More specific guidance is contained in documents such as the Standard Minimum Rules for the Administration of Juvenile Justice ("Beijing Rules") of 1985, Guidelines for the Prevention of Juvenile Delinquency ("Riyadh Guidelines") of 1990 and Rules for the Protection of Juveniles Deprived of their Liberty ("Havana Rules") of 1990. These documents, among many others, describe

Table 49.1 Roles for forensic child and adolescent mental health services (*Mental disorder includes mental illnesses, neurodevelopmental disorders, and substance misuse*).

Time/location	Roles for forensic child and adolescent mental health teams
Arrest	Training police officers in identification of mental disorder in juvenile offenders Effective police liaison for prompt mental health assessments and transfers to psychiatric healthcare settings as required
Juvenile detention	Screening for mental disorder and substance misuse on entry to establishment Assessment and management of inmates/residents with mental disorder Joint working with staff to manage risk and implement care plans Liaison with other agencies for continuity of care and support after release
Trial	Assessment of capacity/fitness to be interviewed, plead, testify or stand trial Recommendation of any special measures to be implemented during trial Opinion on mitigating circumstances and psychiatric defences to alleged offences
Sentencing/disposal	Provision of opinions on: diagnosis of mental disorder, risks, treatment needs, suitability of setting for treatment and management, court-mandated mental health treatment in psychiatric hospital or the community, safeguarding or parenting concerns, social needs or educational requirements.
Secure psychiatric hospital	Provision of age-appropriate secure psychiatric hospital services. Liaison with juvenile prisons, secure residential homes, general children's inpatient units and community services.
Community	Collaboration with youth justice and other community agencies for delivery of mental health care and risk management, delivery of systemic interventions, advocacy for young people and support for protective factors (e.g., education).
Prevention	Collaboration with stakeholders (families, education, healthcare, social services, police and youth justice) in the development of coherent strategies for prevention of juvenile offending, early identification of problems, referral to services and delivery of effective interventions.

ideal standards of juvenile justice that have been implemented to a somewhat inconsistent and limited extent around the world (Goldson & Muncie, 2012).

The degree to which juvenile offenders receive special treatment as juveniles varies across the world, and differences have been highlighted by the growing trend for an international comparative approach (Muncie & Goldson, 2006; Hazel, 2008). Juvenile justice systems have historically been divided into either “welfare” or “justice” models. While “welfare” approaches share a focus on the needs of the child, diagnosis, treatment and more informal procedures, the “justice” approach emphasizes accountability, punishment and procedural formality. In reality, there are elements of both welfare and justice models within most countries. However, there are notable differences in standards of behavior deemed to constitute juvenile offending, the very definition of a youth/juvenile and, particularly significantly, vast differences in the minimum age of criminal responsibility. Many consider that the low age of criminal responsibility of 10 years in England and Wales, and 6 years in several US states, is out of keeping with international norms and criminalizes children at an age that is developmentally inappropriate. The issue continues to be the subject of vigorous debate (Church *et al.*, 2013). Overall, there is a vast array of factors that shape the characteristics of youth justice systems and their development is subject to numerous further influences, not least the prevailing

political ideology and media/public responses to significant adverse events.

Youth justice process

The journey of a young person through a welfare or juvenile justice process can include several stages such as arrest, interviews by officials, official statement of alleged offences, entering a plea, giving evidence, an adversarial or inquisitorial process to determine fact, and disposal or sentencing.

Numerous problems can arise during such a process. Firstly, there is evidence to indicate that children are vulnerable to interrogation and to making false confessions. In a self-report study of 10,472 Icelandic youth, of the 18.6% who reported being interrogated by the police, 7.3% reported having made a false confession. Compared to other suspects, the false confessors reported increased anxiety, depression, anger problems, poorer self-esteem, less parental support, more delinquency during the previous year and more delinquency among friends (Gudjonsson *et al.*, 2006). These findings highlight the importance of support during interrogation, such as the practice of having an “appropriate adult” present when a child is interviewed for a suspected offence in the United Kingdom, or having legal representation (see also Chapters 19 and 20).

Juveniles are also vulnerable during court processes if they lack the ability to understand charges, follow proceedings, work with

their legal representatives or give evidence in their own defence, either as a result of mental disorder or developmental immaturity. A study of 927 adolescents tested for competence to stand trial concluded that one-third of 11–13 years olds and one-fifth of 14–15 year olds performed as poorly as adults with severe mental illness who would be deemed incompetent to stand trial. Furthermore, defendants under the age of 15 years have been found to be more likely to make poor legal decisions, including choices that reflected compliance with authority (Grisso *et al.*, 2003; Viljoen *et al.*, 2005).

In order to cater for the particular needs of child defendants, the United Nations supports the development of specialized systems for managing children in conflict with the law. This has led to the promotion of juvenile courts; however, many countries lack juvenile justice services or specialist legal provision for juveniles.

Disposal and sentencing

The term “disposal” is used to describe all outcomes following contact with the police. This can include a large number of contacts that are dealt with informally by the police, such as with a warning, in which young people are particularly over represented. When a young person is convicted of having committed an offence, they may be sentenced to serve a term in a locked environment, or they may receive any of a number of community sentences with requirements such as fines, community service, reparation work, parenting orders, curfews, exclusions, electronic monitoring, testing, and treatment for substance misuse or mental health treatment requirements.

While there has been a sustained trend toward reducing the number of incarcerated juveniles, this has not been observed consistently in all communities; black and minority ethnic groups continue to be vastly over represented, especially in North America, Australia and New Zealand. Some countries, such as Sweden, have carefully tailored age-dependent sentencing guidelines, tuned to the developmental immaturity of defendants. In particular, a flexible approach around matching court orders to the individual needs of young offenders may be a particularly beneficial model (Vieira *et al.*, 2009). As part of such individualized sentencing, court orders directing mental health treatment in inpatient or community settings can be a valuable care pathway for managing mentally disordered offenders, if permitted under the local jurisdiction. Specialized youth mental health courts may be a helpful model to support multidisciplinary coordination and avoid protracted justice system involvement (Callahan *et al.*, 2012).

A particularly emotive topic continues to be capital punishment (the death penalty) for juvenile offenders; the practice was outlawed in the United States following a landmark ruling in the US Supreme Court in 2005 (*Roper v. Simmons*), but continues in a small number of other countries, sometimes upheld by religious laws.

Restorative justice

The restorative justice approach has grown significantly worldwide over the last 30 years, with diverse local implementation in Australia, Canada, Germany, Japan, New Zealand, United Kingdom and United States. A central theme is the bringing together of the victim and perpetrator of an offence for mediation, with elements of both accountability and reintegration. Family group conferences, first developed in New Zealand, are sometimes considered to fall within a restorative justice model. While this approach may not be applicable to all offences, and may not serve to reduce recidivism, it is associated with high user satisfaction for both victims and perpetrators.

A developmental understanding of juvenile delinquency

Juvenile delinquent is a term commonly used to describe a young person who has broken the law. However, the term is often problematic, and an alternative preferred by the United Nations is “children in conflict with the law”—perhaps reflecting changing understanding and attitudes. The distinction between criminological, social and biomedical research has become somewhat blurred in literature regarding the developmental origins and risk factors for juvenile delinquency. Early criminological cohort studies formulated to explore the precursors of crime have had a strong psychosocial component (Farrington & West, 1971) and epidemiological studies of psychiatric disorder in children have included examination of the risk factors for conduct disorder (Rutter *et al.*, 1975), yielding complementary results. The increased prevalence of conduct disorder in urban compared to rural settings was consistent with an increased urban prevalence of risk factors for development of delinquency. As developmental perspectives of delinquency, including evidence on parenting as an important proximal risk factor, were increasingly explored (Patterson *et al.*, 1989), a broader understanding of antisocial behavior by young people emerged within a biomedical framework (Rutter *et al.*, 1998), informed by a growing stream of follow-up data from large cohort studies (see Chapter 65).

The Cambridge Study in Delinquent Development has now followed up 411 males from age 8 to 50 years with repeated personal interviews and criminal record searches. It provides a rich source of information and analysis of risk factors associated with offending. Early predictors at age 8–10 years for subsequent convictions include low family income, poor housing, large family size, school delinquency, having a convicted parent, a delinquent sibling, having a young mother, a depressed mother, poor child-rearing skills, poor supervision and a disrupted family. Individual factors that predicted offending include low non verbal IQ, low verbal IQ, low attainment, high daring, poor concentration, high impulsivity, low popularity, and both troublesome and dishonest behavior (Farrington *et al.*, 2009a). Bullying has also been identified as a significant predictor of subsequent offending and violence (Farrington & Ttofi, 2011).

Findings from the collation of six large longitudinal studies of children (Montreal, Quebec, Christchurch, Dunedin, Pittsburgh, and the US Child Development Project) indicate that while male childhood physical aggression is the most consistent predictor of both violent and non violent offending, early non aggressive conduct problems also increase the risk of later violent offending. Early oppositional behaviors were observed to independently increase the risk of non violent offending (Broidy *et al.*, 2003).

Results from the Edinburgh Study of Youth Transitions and Crime noted similar well-established risk factors for offending, and highlighted the broad range of vulnerabilities and social adversity in juvenile offenders. It proposed that critical moments in early teenage years influenced pathways into or away from offending, with events such as exclusion from school being particularly deleterious. While the authors support diversion strategies to facilitate desistance from offending, they express concern at the risk of labeling and stigmatizing children judged to be at-risk through early identification (McAra & McVie, 2010).

The widely cited dual taxonomy of adolescence-limited and life course persistent offenders (Moffitt, 1993; Moffitt *et al.*, 2002; see Chapters 4 and 65) is not always fully supported by longitudinal data and the original grouping has since been refined, but has been a helpful framework for the analysis of patterns of offending behavior (Farrington *et al.*, 2009b). The life course persistent group is more likely to have neurodevelopmental impairments, difficult temperament, neurological abnormalities, lowered intellectual capacity and hyperactivity. By contrast, the far more common adolescence-limited group tends to display short-lived antisocial behavior with social origins, such as peer influence and intoxication with alcohol and substances.

As parental delinquency is generally accepted to be a significant predictor of juvenile delinquency, it may be no surprise that parental imprisonment is associated with further poor outcomes (Murray *et al.*, 2009). The finding that persistently delinquent individuals are at risk of having delinquent offspring has sometimes been termed the “cycle of violence,” supported by evidence that constitutional and environmental risk factors contribute to delinquency, that constitutional risks are amplified by adverse rearing environments (see adoption studies, Chapter 12) and by newer evidence of potential gene–environment interactions.

Increased understanding and consensus around risk factors and protective factors for juvenile delinquency has implications for public health research and implementation of strategies to reduce juvenile offending (Loeber & Farrington, 2000; Hall *et al.*, 2012). The benefits of this are potentially far-reaching; the 14 year follow-up report on the Pittsburgh Youth Study showed that many risk factors known to be associated with delinquent behavior also predicted mental health problems (Loeber *et al.*, 2001), indicating that action to prevent juvenile offending might have wider benefits on the mental health of young people.

The mental health of juvenile offenders

Over the last 15 years, the mental health of juvenile offenders has received increasing attention, with numerous psychiatric morbidity studies conducted across the world. Methodological differences hamper effective comparison of studies, but in general significantly elevated levels of psychiatric morbidity have been observed in juvenile offenders across virtually all categories of mental disorder.

A national study of detained young offenders aged 16–20 years in the United Kingdom found that 13% of remanded males had received support for a mental or emotional problem in the 12 months before coming to prison, compared to 27% of females. Nearly 1 in 10 of sentenced female young offenders reported having had a psychiatric hospital admission in the past. High prevalence of psychiatric disorders in sentenced inmates included personality disorder (88%), any psychosis (10%), mood/anxiety disorders (41% of males and 67% of females), lifetime suicide attempts (20% of males and 33% of females), self-harm (7% for males and 11% for females), hazardous alcohol consumption (70% of males and 51% of females) and drug misuse (70%). The proportion of young people taken into local authority care in their childhood was 35% for remanded females and 42% for remanded males. These results are consistent with other studies that consistently identify much higher rates of mood/anxiety disorders and self-harm in female young offenders than in male. Of note, overall at least 95% of all young offenders were identified as having a mental disorder, with comorbidity observed in 80% (Lader *et al.*, 2000).

High prevalence of mental disorder among juvenile offenders has been replicated in the United States (Atkins *et al.*, 1999; Teplin *et al.*, 2002; Shufelt & Cocozza, 2006), Finland (Sailas *et al.*, 2005), Sweden (Fazel *et al.*, 2008a), Switzerland (Gisin *et al.*, 2012) and several other countries, with further support for high psychiatric comorbidity (Abram *et al.*, 2003). Systematic reviews have noted a wide range of prevalence of overall mental illness in juvenile offenders, invariably far higher than found in the general population (Fazel *et al.*, 2008b; Penner *et al.*, 2011).

Neurodevelopmental disorders

In the last decade, the prevalence and severity of neurodevelopmental disorders in young offenders has received greater scrutiny. A study of incarcerated juvenile offenders in the United States identified average prevalence rates for youth with disabling conditions (including “emotional disturbance”) of 33.4%, with 38.6% of these individuals displaying specific learning disabilities and 9.7% mental retardation (Quinn *et al.*, 2005).

A review of neurodisability in young offenders indicated an elevated prevalence of intellectual disability (23–32%, compared to 2–4% of the general population), specific learning disability such as dyslexia (43–57%, compared with 10% of the general population), communication disorders (60–90%, compared with 1–7% of the general population), autism spectrum disorders (15% compared with 0.6–1.2%), traumatic

brain injury (65–76% compared with 5–24%), fetal alcohol syndrome (10.9–11.7% compared with 0.1–5%, and attention deficit/hyperactivity disorder (ADHD; 11.7% for males and 18.5% for females, compared with 1–2% for ICD-10 hyperkinesis or 3–9% for DSM-IV ADHD), (Hughes *et al.*, 2012). Studies of ADHD in young offenders in the United Kingdom and Germany have indicated a higher rate of 43–45% (Rösler *et al.*, 2004; Young *et al.*, 2010). A meta-analysis of the rate of ADHD in young offenders reported a prevalence of 30.1% (Young *et al.*, 2015).

Unmet needs

Despite the known high prevalence of mental disorder, the mental health needs of young offenders are generally not adequately met (Kurtz *et al.*, 1998; Teplin *et al.*, 2005) and even when services are available, may not be accessed equally by offenders of all racial groups (Rawal *et al.*, 2004). The stakes could not be higher: a high suicide rate has been observed in young male prisoners (Fazel *et al.*, 2005) and the elevated general mortality rate of young offenders sentenced to prison is associated with mental disorder (Sailas *et al.*, 2006). Furthermore, while the presence of a psychiatric disorder in detained adolescents alone may not represent a risk factor for serious recidivism (Colins *et al.*, 2011) better mental health services may reduce the risk of future juvenile justice system involvement (Foster *et al.*, 2004).

Building on knowledge of high prevalence of mental disorder, investigative tools such as the Salford Needs Assessment Schedule for Adolescents have been used to highlight the substantial rates of unmet mental health and psychosocial needs for boys in secure care (Kroll *et al.*, 2002; Harrington *et al.*, 2005) and young offenders (Chitsabesan *et al.*, 2006).

The relationship between mental disorder and juvenile offending is not always clear and merits further investigation. Some evidence indicates that juvenile mental health users are more likely to come into conflict with the law, having more arrests than non mental health service users (Rosenblatt *et al.*, 2000). In the case of ADHD (and most likely several other mental disorders), the associated increase in juvenile offending may not be directly related to the disorder but mediated indirectly by comorbidity with conduct disorder, substance misuse and peer delinquency (Gudjonsson *et al.*, 2014).

Forensic psychiatric assessment of juveniles

Principles of assessment

The broad range of needs and risks presented by juvenile offenders puts particular demands on the clinician, with a requirement for a thorough assessment, information from collateral sources, timeliness, clear notes, clear risk assessments, clear management plans, good communication with other disciplines and agencies and arrangements to maintain continuity of care. A clinical history should include a developmental history, with information from multiple sources including family, paediatrics, family doctor, education, social services, youth justice agencies,

police and not least, from the young person themselves (see Chapters 32–35).

A forensic psychiatric assessment should include consideration of conduct disorder, depressive and anxiety disorders, suicidality and self-injurious behavior, post traumatic stress disorder, substance misuse, psychotic disorders, ADHD, language and communication disorders, cognitive impairment and autism spectrum disorders. The ICD-10 multiaxial diagnostic system for children and adolescents (see Chapter 2) is particularly well suited to this population.

The primary difference from a regular (non forensic) child psychiatric assessment lies in the need to assess criminogenic factors and their association with underlying psychiatric conditions. These factors may include the perception of the circumstances of the antisocial behavior/crime, the role they played in the behavior/alleged offence and that of others, antecedents and consequences of the behavior, their attitude, and beliefs toward the behavior/crime, level of remorse and blame attribution. Obtaining this history may be complicated by many factors, including a reluctance to fully engage in the assessment, a lack of openness and honesty, a tendency to give socially desirable responses, perceived peer pressure and fear of reprisals.

It is not feasible to conduct a comprehensive psychiatric assessment for all juveniles who come into contact with a youth justice system. The practice of screening for mental disorder has therefore been adopted, using instruments such as the Massachusetts Youth Screening Instrument (MAYSI; Grisso *et al.*, 2001) and by embedding mental health screening into youth justice policy and routine practice (Bailey *et al.*, 2006). In the United Kingdom, the Department of Health is introducing the Comprehensive Health Assessment Tool (CHAT) across young offender establishments.

Effective awareness of and screening for anxiety and depression as well as suicidal risk may be particularly important as they are often overlooked in secure environments (Mitchell & Shaw, 2011). This is particularly necessary when assessing females who more commonly present with emotional disorders (see Chapters 58–64). For disruptive and neurodevelopmental disorders, screening by self-rating and informants is helpful for identifying cases requiring further assessment (Young *et al.*, 2010).

A set of healthcare standards for children and young people in secure settings published in the United Kingdom notes the importance of physical and mental health care in this population, including attention to history of vaccinations, nutrition, dental health and continuity in care for ongoing conditions (Royal College of Paediatrics and Child Health, 2013).

Risk assessment

Risk assessment, risk formulation and risk management may be considered to be among the core tasks of forensic child and adolescent psychiatrists. As with general assessment, risk assessment depends on obtaining a good history from multiple sources. The commonly encountered risks associated with juvenile offenders are listed in Table 49.2. Many young offenders are at risk of victimization themselves; a high proportion will

Table 49.2 Types of risks.**Risks to self**

Neglect by carer or self-neglect
 Abuse (emotional, physical, or sexual, including exposure to domestic violence)
 Substance misuse (acute intoxication, longer term harm and withdrawal)
 Self-harm (self-cutting, overdoses, burning, insertion, ligatures and suicide attempts)
 Exploitation (coercion, financial and sexual)
 Vulnerability arising from mental disorder or homelessness
 Reprisals from victim or parties linked to victim
 Gang-related violence

Risks to others

Violence (pushing, punching, slapping, kicking, biting and strangling)
 Use of weapons (blades, firearms, makeshift weapons e.g., chairs, biological weapons e.g., blood or saliva, harmful chemicals e.g., hazardous cleaning materials)
 Emotional abuse and bullying (personal, racial, ethnic, religious or sexual themes)
 Electronic aggression (cyberbullying, cyberstalking or cyberharassment)
 Sexually harmful behavior (exposure, touching, penetration and indecent images)
 Stalking
 Unsafe fire setting (accidental, impulsive, planning, method, fuel, disabling alarms and blocking exits)
 Criminal damage
 Theft/burglary
 Vehicle offences (no licence, no insurance and “joy riding”)
 Substance-related offences (possessing, using, selling and trafficking)
 Fraud (identity and financial)
 Non compliance and breaching community orders
 Subversion of security (tampering with alarms, locks, doors and cybersecurity)
 Escape from secure setting or absconson/running away
 Hostage taking (likely targets and demands)
 Concerted disorder (coordinated antisocial acts, riots, instigator or follower)

have been subjected to abuse of various forms at the hand of their carers, and these safeguarding risks may require urgent action (see Chapters 29 and 30). Gang membership is known to be an important risk factor for delinquency (see Chapter 12). Gang-related tensions and risks of reprisals following offences may also pose significant risks that authorities must consider. Furthermore, juvenile offenders may be vulnerable to exploitation by others due to neurodevelopmental problems or other mental disorder.

Risk of violence to others

Most risk assessments assess risk of future violence to others. The “risk formulation” is a statement of the risk—a description of the current nature, severity, likelihood and immediacy of an adverse event, combined with an analysis of factors that are likely to modify the risk, and a plan for monitoring or review of risk. In particular, an analysis of past events is essential as past behaviors are the best predictor of future behaviors; important factors include planning, weapons, motivation, intention, discoverability, substance misuse, mental disorder and peer influence.

Three main approaches to risk assessment are generally acknowledged: clinical judgements, actuarial risk assessments

and structured professional judgements. A clinical judgement on risk is a fast but unstructured risk assessment; there are no requirements around the minimum information required, and the quality of the assessment depends very much on the practitioner performing it. Actuarial risk assessments are statistically determined tools that use historical information to predict risks of reoffending; they may be more reliable than clinical judgement and a meta-analysis of their predictive validity indicates some potential benefit (Schwalbe, 2008). However, actuarial tools are rather static; they do not take account of changeable clinical factors and do not indicate points for interventions. Hence, the third method is the most commonly applied in practice, structured professional judgement tools that include items that have been statistically associated with violence. The Structured Assessment of Violence Risk in Youth (SAVRY; Borum *et al.*, 2005) combines historical factors (e.g., history of violence) with dynamic social (e.g., peer delinquency), individual (e.g., substance misuse) and protective factors (e.g., strong commitment to school) that lead very naturally to a risk management plan. For younger children, the gender-specific Early Assessment Risk List (EARL; Augimeri *et al.*, 2010) is also used widely.

The term “violence” encompasses a wide range of acts from slapping to homicide, with or without weapons. A useful distinction is often made between instrumental (planned or proactive) aggression and reactive (affective, defensive or impulsive) aggression. While instrumental aggression is classically associated with low anxiety and psychopathic traits, reactive aggression is associated with angry outbursts, mood dysregulation and disorders such as ADHD. Markers of psychopathy in children and adolescents typically assess behaviors categorized as callous and unemotional, as there have been concerns about applying the term “psychopathy” to juveniles. Callous and unemotional traits are widely accepted as a significant risk factor for violent offending (Farrington and Welsh, 2005) and are now included within the DSM-5 conduct disorder specifier of “limited prosocial emotions.” Psychopathy in young people can be assessed using the Psychopathy Checklist Youth Version (PCL:YV; Forth *et al.*, 2003). Some have argued that while useful, the construct of childhood psychopathy deserves greater scrutiny, with more attention to potentially dynamic developmental aspects that may contribute to an individual’s apparently callous or unemotional presentation (Cooke *et al.*, 2004; Dawson *et al.*, 2012). See Chapter 68.

Sexually harmful behavior

Tools for assessing risk of sexually harmful behaviour include the Juvenile Sex Offender Assessment Protocol II (J-SOAP-II; Prentky & Righthand, 2003) and Estimate of Risk of Adolescent Sexual Offense Recidivism (ERASOR; Worling & Curwen, 2001). The AIM (Assessment, Intervention, and Moving on) program, based on the Good Lives Model (GLM), has been gaining popularity as an approach that draws on the young person’s strengths to undertake a comprehensive assessment

and to deliver treatment (Griffin *et al.*, 2008). An appreciation of developmental and gender aspects of sexuality is essential for this sort of assessment. A behavioral analysis approach (i.e., a functional analysis of behavior) may be more suitable for individuals with significant intellectual disability and sexually harmful behavior.

Unsafe fire setting and arson

Unsafe fire setting by adolescents should be considered within a developmental framework (MacKay *et al.*, 2012), with particular attention to intent and planning (Table 49.2). The assessment must include a behavioral analysis of the antecedents and consequences of the behavior in order to gain a comprehensive understanding of the factors and beliefs influencing behavior, so as to identify targets for intervention. Female juvenile fire setters may present increased mental health needs and risks (Hickle & Roa-Sepowitz, 2010). Arson is a legal term and a young person may be convicted of attempted arson even in the absence of actual fire setting.

Emotional abuse and stalking

Emotional abuse, bullying and harassment including stalking (Purcell *et al.*, 2009) may take a variety of forms and themes. Cyberbullying, cyber-harassment and cyberstalking via electronic media are increasingly recognized as a serious form of victimization (Ybarra & Mitchell, 2004; Patchin & Hinduja, 2006; Kiriakidis & Kavoura, 2010) and one that may deserve special attention in risk assessment.

Risk management

It is important to be mindful that the objective of a risk assessment is to generate a risk management plan that has a constructive and applied purpose to reduce risk as opposed to an overarching prediction of the likelihood of reoffending. This will include strategies for reducing and managing risk behavior(s), including the need for specific monitoring, treatment, support, disclosure and consideration of the need for multi-agency involvement. It should be integrated into the general care plan for the young person, shared with all relevant professionals and agencies and updated every 6–12 months especially for change in dynamic factors to assess need for physical security (locks, doors, and alarms), operational security (procedures, and protocols) and relational security (good clinical knowledge of the young person and a therapeutic relationship between patients and staff).

Interventions

Principles of intervention

Interventions in criminal justice systems often operate under the risk-need-responsivity (RNR) model, which focuses on the prediction of risk and classification of offenders for treatment (Andrews *et al.*, 1990). This model identifies those presenting highest risks to others as candidates for the most intense

intervention. A contrasting approach known as the GLM (Ward & Brown, 2004) presents a positive, restorative model of rehabilitation based on strengths. This makes for a more customized intervention focused on prosocial ways of meeting the particular physical, social, and psychological needs of an individual. In parallel to these developments, the consideration of juvenile delinquency within a public health approach shifts young people into a biomedical sphere where evidence-based interventions are considered for the primary, secondary and tertiary prevention of juvenile delinquency (Stevens *et al.*, 2006). Primary prevention encompasses universal approaches to prevent crime before it occurs; secondary prevention focuses on those at highest risk of offending; tertiary prevention consists of approaches with young people who have already offended (Table 49.3).

Given the mental health needs in young offenders, support for mental disorders should be included as a central component of any intervention (see individual disorder chapters). Furthermore, the high prevalence of disturbed early attachments and post traumatic stress should be considered in the delivery of appropriate interventions (Kerig *et al.*, 2009). There has been some support for extending the concept of attachment styles into adolescence (Scott *et al.*, 2011) and this may represent a helpful framework for assessing and understanding the interpersonal styles and difficulties of juvenile offenders.

Evidence for early interventions

Findings from the Cambridge Study in Delinquent Development identified four targets for early intervention: (i) low intelligence/attainment, which can be targeted by preschool

Table 49.3 A public health model for youth offending.

Primary prevention

Parenting programs
Preschool programs
Day-care programs
School programs
Cognitive skills training
Peer programs
Community programs
Situational crime prevention

Secondary prevention

Family-focused therapies
Mentoring
Therapeutic foster care
Safeguarding of children
Treatment of parental substance misuse

Tertiary prevention

Cooperation between police, social services and mental health
Intensive supervision and surveillance
Assertive treatment of mental disorder
Restorative justice
Victim support

Source: Adapted from Stevens *et al.* (2006).

intellectual enrichment programs; (ii) poor parental child-rearing behavior, which can be targeted by parenting programs as early as pregnancy; (iii) impulsiveness, which can be targeted by cognitive-behavioral skills programs; and (iv) poverty, although there is little evidence to support reduced juvenile delinquency resulting from income maintenance (Farrington *et al.*, 2009a, b). Programs for early family and parent training show beneficial effects on delinquency and problem behaviors (Scott, 2005; Piquero *et al.*, 2008; see Chapter 37); strategies that support children under 10 to improve self-control have also been suggested (Piquero *et al.*, 2010). Many of these treatments overlap with those for conduct disorder (see Chapters 36, 37 and 65). Recently published national guidelines for treatment of antisocial behavior and conduct disorders in the United Kingdom are helpful (National Institute for Health and Care Excellence, 2013).

Systemic interventions

Among the best known interventions for those at risk of juvenile offending is multisystemic therapy (MST) which was developed to be an effective alternative to incarceration (Henggeler *et al.*, 1992). It consists of an intensive set of integrated interventions across multiple systems in the young person's life, following nine treatment principles such as using strengths in the young person's environment as levers for change and promoting responsible behavior in the family. Support for MST in juvenile offending has emerged from independent effectiveness trials (Timmons-Mitchell *et al.*, 2006) and cost-effectiveness analysis (Cary *et al.*, 2013). However, meta-analytic reviews reveal several trials that failed to replicate its effectiveness (Littell *et al.*, 2005). The training requirements, intensity of the work and strict requirements around fidelity to the treatment model can sometimes hamper implementation (see Chapter 50).

Multidimensional treatment foster care (MTFC) was formulated within a social learning model. It uses a foster home as the primary site of therapeutic intervention, encouraging contact with prosocial young people. There are high levels of clinical support, daily contact and points systems for rewards alongside clear consequences for negative behavior. General therapeutic foster care has been suggested as being effective in the prevention of violence (Hahn *et al.*, 2005) although evidence from randomized controlled trials is mixed (see Chapters 50 and 65). Another manifestation of an intensive systemic approach is the "wraparound" process designed to support children and their families (Suter & Bruns, 2009). The meta-analysis by Lipsey (2009) of 548 diverse intervention studies found three factors that predicted success: a "therapeutic" intervention philosophy, serving high risk offenders and good quality implementation.

Psychological and offending behavior programs

Structured programs using a cognitive-behavioral model have been associated with marked reductions in recidivism in high risk detained males (Tong & Farrington, 2006; Garrido *et al.*, 2007). On the other hand, more modest benefits have been

reported when delivered in residential settings (Armeliuss & Andreassen, 2007). Specific cognitive-behavioral programs developed for juvenile delinquents may be more promising and require further evaluation, such as Anger Replacement Training (ART; Glick & Goldstein, 1987) and the revised Reasoning & Rehabilitation (R&R2; Young & Ross, 2007a, b).

For working with perpetrators and victims of sexually harmful behavior, the manualized AIM program has been gaining popularity in the United Kingdom. This includes a repertoire of numerous modules for males, females, young children, children with intellectual disability, schools and foster carers. Based on the GLM, it draws on the young person's strengths to undertake a comprehensive assessment and deliver treatment (Griffin *et al.*, 2008). Clinicians should be alert to the high proportion of juvenile sexual offending that occurs against other children and the higher likelihood of complex needs during the assessment and treatment of females who display sexually harmful behavior (McCartan *et al.*, 2011).

Other psychological interventions with some evidence of effectiveness include school-based programs for social skills and information processing (Wilson & Lipsey, 2006), mentoring (Tolan *et al.*, 2008) and leisure time activities for youth at risk (Danish Crime Prevention Council, 2012). There has also been a rise in programs aiming to tackle and prevent gang-affiliation.

Substance misuse programs for young people are widespread, but meaningful engagement and motivation to change are often an obstacle. The technique of motivational interviewing for treatment of substance misuse (Miller & Rollnick, 1991) is a promising approach that has been applied to juvenile offender populations but requires further investigation (Feldstein & Ginsburg, 2006). Limited data from studies of youth drug courts indicate a modest reduction in recidivism (Mitchell *et al.*, 2012). See Chapter 66.

Special consideration should be given to individuals with neurodevelopmental disorders, who may not find it easy to access the services they require, or may need environmental or procedural modification to help manage their risk or vulnerability. A study looking at the language and communication skills of juvenile offenders found that 66–90% of the sample had below average language skills, with 46–67% of these being in the poor or very poor range, suggesting that these young people may not have the necessary skills to cope with verbally mediated interventions aimed at reducing reoffending (Bryan *et al.*, 2007). Clinicians must therefore be alert to these potential barriers preventing young people from participating in therapeutic programs, particularly in group settings. Intervention by a speech and language therapist may help improve confidence, communication skills and engagement in therapeutic programs (see Chapters 51–57).

Medical interventions

Aside from addressing criminogenic needs, individuals with mental disorder should be treated for psychiatric conditions

in the usual way (see chapters for clinical syndromes and personality disorder). For young offenders with severe psychiatric disturbance and complex needs, secure psychiatric hospitals provide a safe and contained setting for intensive assessment, treatment, and management, with a multi disciplinary and multi-agency focus.

Due to the high prevalence of neurodevelopmental disorder, traumatic brain injury and elevated rates of alcohol and substance misuse in young offenders, clinicians may wish to be cautious when prescribing psychotropic medication in view of constitutional sensitivities and interactions with substances. Other challenges include the potential for non concordance with medication, sequestration of tablets for overdose, taking irregular or excessive doses, trading of tablets and potential for abuse. Supervised medication delivered in liquid or orodispersible formulations may sometimes be most appropriate.

Moreover, there may also be a role for the use of pharmacological treatment in the rapid tranquilization of acutely mentally disturbed aggressive young people, as described in established guidelines (Taylor *et al.*, 2012). However, efforts should be made to avoid such a situation by early identification of distress, engaging the patient, establishing a therapeutic rapport and considering environmental modification to help de-escalate a situation. The preferred method of managing severe aggression in young patients varies between countries; the United Kingdom routinely implements physical restraint by staff and seclusion, but there is a degree of reluctance and caution in the use of rapid tranquillization of juveniles and virtually complete avoidance of mechanical restraint. Some other countries use mechanical restraint more liberally, with much less use of seclusion for juveniles.

Unhelpful interventions

Well known but discredited approaches include “Scared Straight” programs in which juveniles at an early stage of offending are exposed to high security prison inmates; there is evidence that this approach may actually increase risk of recidivism, compared to no intervention (Petrosino *et al.*, 2004). Another example is correctional military style boot camps with harsh discipline. Moreover, trying juveniles in adult courts, juvenile curfews and probation are cited as measures that are not effective in preventing juvenile crime (Stevens *et al.*, 2006).

Professional considerations

Whether for criminal or civil proceedings including family, child custody, immigration or mental health law, a psychiatric expert who prepares a report for court must adhere to standards of integrity and professionalism expected by their professional body (see Chapter 19). Depending on the jurisdiction, a forensic psychiatrist may be instructed to provide a report on pretrial issues such as fitness to plead and special measures for effective participation, trial issues such as psychiatric defences and mitigating circumstances, opinions

on risk and recommendations on disposal or care pathway. Further information, including practical guidance, is available in specialist textbooks (Bailey & Dolan, 2004; Benedek *et al.*, 2009; Young *et al.*, 2009; Rix, 2011).

Ethical dilemmas facing the forensic psychiatrist

It has been argued that objectivity is almost invariably compromised when a treating practitioner presents medical evidence to court about their patient. This position creates a compelling need for independent experts, who bring not only enhanced objectivity to proceedings but also specialist medicolegal skills and experience. The United States probably provides the best example of where the practice of such “forensicians” has become firmly established and hotly debated. Disagreement has emerged around the extent to which these largely court-bound professionals ‘practice medicine’ in their advisory role. The Ethics Committee of the American Psychiatric Association has brought some clarity to the matter by stating that “psychiatrists are physicians, and physicians are physicians at all times,” affirming the medical responsibility of professionals to patients wherever they practice. Indeed, the duty of care to the patient and the duty to protect the public from harm are often in harmony, as effective treatment and management strategies tend to address both types of risk simultaneously. Furthermore, such a role may be considered as lying outside the professional remit of the treating clinician and/or the treating psychiatrist may simply not have the time or resources to provide specialist advice to courts.

For these and other reasons, it is most likely that independent experts will continue to be required in court proceedings. Measures should therefore be in place to help legal teams and courts appoint appropriately qualified experts, who are competent and clinically active in the relevant field. In cases involving children and adolescents, court experts should demonstrate competence, experience and up-to-date knowledge of working with children. Experts should not stray outside of their area of expertise, for example, by giving ‘bedside’ estimates of IQ or by interpreting psychological test results when not trained to do so. It is important that effective professional collaborations are developed with other disciplines, for example, with clinical, forensic and/or neuropsychology.

Conclusions

Forensic child and adolescent psychiatry has emerged as a significant clinical subspecialty, straddling the interface between child and adolescent psychiatry, forensic psychiatry, and the law in a clinically and ethically challenging, multidisciplinary and multi-agency setting. This chapter has provided an introduction to this clinical subspecialty with the hope that it will encourage readers from psychiatry and allied disciplines to engage with a vulnerable population of young people whose needs and rights are so often overlooked across the world, and for whom early intervention may be life-changing.

Acknowledgments

The authors thank David Farrington for helpful correspondence that supported the writing of this chapter.

Provision of intensive treatment: intensive outreach, day units, and in-patient units

Anthony James¹ and Anne Worrall-Davies²

¹Department of Psychiatry, University of Oxford, UK

²Adolescent Inpatient Service, Leeds Community Healthcare NHS Foundation Trust, Leeds, UK

Introduction

Intensive community services and inpatient care are essential components of a comprehensive child and adolescent mental health service (CAMHS), particularly for those more severely disturbed children and adolescents and for those at risk of self-harm, suicide, or harm to others. Intensive community services form an increasingly important level of care between outpatient and inpatient services. Often these services can provide more immediate and flexible local care, sometimes on a home basis, to a greater number of children and adolescents. Inpatient care remains an economically costly but essential part of a CAMH service and has become specialized, often dealing with greater complexities and more violent children and adolescents. In this chapter, we present community models of intensive services first, followed by day programs, and inpatient models, to reflect increasing intensity and level of restriction.

Community intensive services

Historical development

Changing philosophical beliefs among health, education, and social care professionals, alongside a growing service user movement, have led to the development of a range of community alternatives to day and residential psychiatric care, sometimes specifically to reduce the need for hospitalization or residential care, sometimes to allow more patient choice, or to promote active involvement in care. These alternatives include multisystemic therapy (MST), treatment foster care (TFC), case management, and home treatment. While MST and TFC were developed specifically for young people, case management and home treatment have been adapted from adult models of care. The diverse development of these services makes comparison between them difficult, and this has proved a limitation to

robust controlled studies assessing their relative effectiveness. Two other key factors have limited comparison studies of community services: the “treatment as usual” comparator against which community intensive treatments are measured is often poorly defined and can vary widely from study to study; and at least in early studies, the samples comprised young people not at the highest risk (Mattejat *et al.*, 2001).

Overall principles

Although community intensive models vary widely, they share key characteristics (Smyth & Houlst, 2000; Shepperd *et al.*, 2009; Sjolie *et al.*, 2010; Williamson & Marshall, 2010). Most community intensive services have a defined remit. This may be to prevent hospitalization, as in the case of a home treatment or outreach model, or to prevent delinquency and repeat offending, as in MST or TFC. Operationally, such services are able to respond rapidly (within hours or same working day) and staff are generally available outside the nine-to-five working day, sometimes 24 hours a day, 7 days a week. Low caseloads (typically less than ten cases per fulltime worker) allow flexible working with families and their networks in a range of settings, including the family home, school, and other nonhealth bases such as drop-in centers. Face-to-face or telephone contacts by staff with families are frequent, a minimum three times a week but may be several times a day. Staff undertake assessment, care planning, and treatment delivery to young people and their families, with multidisciplinary team input as and when appropriate. Staff have a detailed knowledge of the services offered by key partner agencies in their locality and will have good relationships with those agencies, which may be statutory, independent, or third sector and reciprocal protocols will exist between them to ensure easy referral pathway.

Evidence for effectiveness of community intensive services is summarized in Table 50.1.

Table 50.1 Defining characteristics of specific community intensive services and evidence to support effectiveness.

Service	Defining characteristics	Key evidence for effectiveness
Multi Systemic Therapy (MST)	Strictly manualized treatment program	<i>Review:</i> Henggeler & Sheidow (2012): early efficacy studies supported by recent positive findings. (Littell <i>et al.</i> , 2009; Pane <i>et al.</i> , 2013): improvements not sustained over time
Treatment Foster Care (TFC)	Reliance on trained professional foster caregivers to deliver prescribed interventions	<i>Systematic review:</i> Macdonald & Turner, 2008; Leve <i>et al.</i> (2009) and Chamberlain <i>et al.</i> (2008): clinically meaningful reductions immediately posttreatment in levels of antisocial behavior, although not well sustained at follow-up
Home treatment	Emphasis on preventing hospitalization or reducing length of stay	<i>Individual studies:</i> Winsberg <i>et al.</i> (1980); Mattejat <i>et al.</i> (2001) suggest home treatment as clinically effective as hospitalization
Case management	Emphasis on a single case manager coordinating or delivering treatment	<i>Meta-analysis:</i> (Suter & Bruns, 2009): inconclusive findings concerning effectiveness of wraparound
Family preservation services (FPS)	Emphasis on preventing family breakdown Manualized program	<i>Systematic review:</i> Shepperd <i>et al.</i> (2009): small clinically significant effects postintervention not maintained at 6-month follow-up <i>Review:</i> Bowyer, 2009: programs with high model fidelity can mediate the consequences of early adverse life events and abuse <i>Meta-analyses:</i> (i) Nelson <i>et al.</i> (2009): programs with high model fidelity significantly reduce family breakdown (ii) Lindsey <i>et al.</i> (2002). Less evidence of efficacy shown by studies with more robust methodologies
Dialectic Behavior Therapy (DBT)	Manualized program	<i>Review:</i> MacPherson <i>et al.</i> (2013) suggests clinical improvements sustained 1 year postintervention

Community intensive services based on specific models

Multisystemic therapy

MST is an intensive approach to working with young offenders presenting with serious antisocial behaviors, at risk of being placed out-of-home. MST clinicians work with the young person in their community and are on call 24 hours a day, 7 days a week, working intensively with caregivers to give them back parental control, to help their child focus on gaining educational and social skills, and to replace maladaptive unstructured activities (“hanging out”). MST has translated successfully globally across a range of cultures including New Zealand, Scandinavia, and the United Kingdom (Ogden and Hagen, 2006; Gustle *et al.*, 2007; Curtis *et al.*, 2009; Wells *et al.*, 2010). MST has systems theory at its base and is a strictly manualized intensive intervention, time-limited to 4 to 6 months.

MST is one of the better-evidenced community intensive treatments for young people, although pooled analyses do not wholly support the strong positive outcomes reported by individual studies and it is not widely available. Henggeler and Sheidow’s review (2012) concluded that the positive findings of early efficacy studies had been sustained in more recent research, namely reduction in offending behavior, substance misuse, recidivism, and psychiatric symptoms, and improvements in school attendance and self-reported improvements by young people and their families (Borduin *et al.*, 2009; Letourneau *et al.*, 2009). Three main factors predict positive outcomes: adherence by staff to the MST model, supported through robust clinical supervision and regular professional

development (Schoenwald *et al.*, 2008; Schoenwald *et al.*, 2009), adherence by families to the program, (Henggeler *et al.*, 2009; Boxer, 2011) and treatment of maternal depression (Grimbos and Granic, 2009). However, two systematic reviews (Littell *et al.*, 2009; Pane *et al.*, 2013) showed data that were of mixed quality revealing inconclusive findings. There was no evidence that MST has harmful effects but little to support the effects of MST being well sustained over time. Study sample sizes for both these reviews were small and the effectiveness findings inconsistent.

Treatment foster care

TFC comprises structured intensive therapy for adolescents with severe antisocial and delinquency problems whose birth family placement has broken down. TFC is delivered by specially trained and salaried foster families who look after just one child at a time. They receive robust supervision and support from TFC specialists and mental health practitioners to ensure that the treatment plan is followed and that services are coordinated round the child. Therapeutic work with the child and foster parents is based on “ABC” principles (antecedents, behaviors, and consequences) and follows comprehensive functional analysis of problem behaviors (see Chapters 21 and 37). TFC has translated with some difficulties outside North America, often in an altered format, and with difficulties in recruiting and retaining foster caregivers (Gustle *et al.*, 2007; Chamberlain *et al.*, 2012).

Pooled analyses and a recent study (Green *et al.*, 2014) suggest that the evidence base is less robust than individual studies indicate. Macdonald and Turner's 2008 review of five studies (total of 390 participants) all conducted by TFC program developers found clinically meaningful reductions posttreatment in levels of antisocial behavior, the number of days young people ran away from their placements, and the time they spent in locked settings (Macdonald & Turner, 2008). Young people spent more time in school and had better rates of homework completion and employment posttreatment. Individual studies (Chamberlain *et al.*, 2008; Leve *et al.*, 2009; Biehal *et al.*, 2012) concur, although the improvements may not be sustained postintervention due to re-engagement of young people with delinquent peers and attrition of consistency in parental discipline.

Case management

The case management model originated as assertive outreach in Wisconsin in the late 1960s: a "hospital without walls" for adult patients (Stein and Test, 1980). Case management has been adopted in the United States and United Kingdom, several European countries and Australia. The three main models of case management are assertive outreach, intensive case management, and wraparound. Assertive outreach employs a flexible approach to engaging and working with severely mentally ill young people in their own community, offering a potentially more accessible service than a traditional mental health service provision (Sainsbury, 2001). Intensive case management shares many key features with assertive outreach, but case managers are more likely to "broker" services rather than provide them directly (Werrbach, 1996). Wraparound services deliver an individually tailored package of care with an emphasis on family strengths. Services are provided through teams that link children, families, and foster parents and their support networks with child welfare, health, mental health, education, and the criminal justice services to develop and implement comprehensive support plans (Suter and Bruns, 2009).

The evidence base for case management approaches is small and yields mixed findings. The one meta-analysis of wraparound services (Suter and Bruns, 2009) showed small treatment effects and could not support or refute the effectiveness of wraparound. Individual studies show varied results. Morthorst *et al.* (2012) reported no significant difference in self-harm repetition rates in adolescents randomized post-self harm episode to treatment as usual or assertive outreach at 12-month follow-up. Conversely, young people posttreatment had clinically meaningful improvements (rated on the Children's Global Assessment Scale, the Brief Symptoms Inventory and Health of the Nation Outcome Scales for Children and Adolescents), a twofold reduction in hospitalization rate and twofold increase in fulltime education (Slesnick *et al.*, 2008; Simpson *et al.*, 2010; Rots-de Vries *et al.*, 2011a, b; Chia *et al.*, 2012).

Intensive home treatment

Intensive home treatment delivers rapid assessment of young people with mental illness in crisis and eligible for hospital admission, with the intention of offering comprehensive acute psychiatric care at home (NIMH, 2004). The primary aim is to avoid or shorten hospitalization through reducing psychiatric symptoms and psychosocial problems. The approach is child and family centered; models used include intensive family therapy and solution-focused approaches.

There are only two published, randomized controlled trials (Winsberg *et al.*, 1980; Mattejat *et al.*, 2001) comparing home treatment with inpatient psychiatric admission. A third trial, of the home treatment program across Connecticut, will be reported in 2015 (Woolston, <http://clinicaltrials.gov/ct2/show/NCT01567969>).

Mattejat *et al.* (2001) reported on 92 young people (mean age 12 years, M:F 2:1) with a range of psychiatric diagnoses including habit disorders, eating disorders, conduct and emotional disorders, and attention deficit hyperactivity disorder (ADHD). Immediately postintervention, the treatment effect sizes for young people allocated to home treatment or hospital admission were similar. However, only 15% of the allocated home treatment group was able to complete the intervention. The remaining 85% needed to be transferred for inpatient treatment because of presence of severe psychosis or a life-threatening eating disorder, severe risk-taking behaviors, or their families lived too far away from the unit for home treatment to be possible logistically. Two to five years later, the observed treatment effects had diminished equally for both groups. However, home treatment remained as effective as inpatient treatment across diagnoses in reducing symptom scores and improving psychosocial functioning. The young person's compliance with the interventions and the therapist skill were the two most important predictors of treatment outcome.

Winsberg *et al.* (1980) evaluated a home treatment intervention for children (5–13 years) with severe emotional and behavioral disorders referred for an inpatient admission, each child spending between 1 and 3 weeks in hospital before randomization to home treatment or further inpatient stay. Intensive home treatment was delivered by case workers supervised by a child psychiatrist, with consultation from an educational psychologist. At 1–3 year follow-up of the entire original sample, 50% of children treated in hospital were living at home compared with 72% of children who had been treated in the community. Parental satisfaction levels with home services and inpatient care did not differ significantly.

Family preservation services

Family preservation services (FPSs) are based on the Homebuilders® model for crisis intervention (Wilmshurst, 2002). This intervention is family focused and community based, aimed at preventing out-of-home placement for children at high risk. Interventions include reframing of problems, anger management, and cognitive behavioral therapy. FPSs have extended

into Europe and Australia, but programs are becoming less popular even in the United States because of the lack of robust outcomes evidence. Two reviews and two meta-analyses conclude that the efficacy evidence for FPS is not as robust as that suggested in early studies (Bowyer, 2009). Close adherence of the program to the Homebuilders® model significantly reduces family breakdown but with varying effect sizes from -0.14 to $+0.77$ across nine studies (Nelson *et al.*, 2009) and the improvements in family functioning and children's emotional problems may not be sustained postdischarge. (Shepperd *et al.*, 2009) The more robust the research study, the less compelling the evidence for FPS's effectiveness (Lindsey *et al.*, 2002). Family-based and program-based factors predict positive outcomes (Berry *et al.*, 2000; Littell & Schuerman, 2002; Ryan & Schuerman, 2004; Bagdasaryan, 2005; Gockel, 2008; Nelson *et al.*, 2009; Tully, 2008). Program-based factors include high intensity of contact (12–15 hours a week), very low caseloads (two families per worker), clear targeting of problems, and a strong therapist-family relationship, perceived as nurturing by families. Family-based factors include presence of two parents in the home, imminent risk of foster placement preintervention when families were highly motivated to change, and absence of parental health problems.

Intensive services based on dialectical behavior therapy

Dialectical behavior therapy (DBT) is an intensive service model based often on the manualized version for adolescents (Miller *et al.*, 2007). It is based on the adult DBT model, which posits emotional dysregulation as a central feature of many psychiatric problems, eating disorders, repeated self-harming behaviors, mood disorders, and emergent borderline personality disorder (Aldao *et al.*, 2010). Empirical theory states that this arises out of an innate biological vulnerability (often observed as impulsive behavior in childhood) plus an “invalidating environment” characterized by negation, punishment, lack of understanding of a child's internal experiences, inconsistent responses, and over-simplification of problem-solving shown by main caregivers. Young people arrive at adolescence not having learned how to regulate emotions (see Chapter 5). A DBT program typically might include weekly individual therapy and weekly groups work in which young people learn and hone skills including how to accept distress and pain, how to manage healthy relationships, adaptive ways to deal with emotional crises; mindfulness meditation, and mentalization. Multifamily work, telephone coaching, outreach strategies, and a weekly consultation team meeting help keep the program on track (James *et al.*, 2008, 2010a).

Outcome research is in the early days. Results of randomized controlled trials of DBT comparing it to other modalities or treatment as usual are awaited. MacPherson *et al.* (2013) evaluated 18 studies, suggesting that across a range of psychiatric problems and in diverse settings (outpatient through intensive provision) DBT in adolescents shows promising outcome: over 8–12 months follow-up, there were reduced rates of psychiatric symptoms and suicidal ideation and actions.

Day programs (partial hospitalization)

Day programs developed in the 1940s and remain a cornerstone of CAMHS especially in North America, but in many low and middle income countries (LMIC) and developing countries, they are scarce or nonexistent. In the last decade, the development of community-based intensive services has put pressure on day programs to justify their existence and focus their role more tightly.

What do day programs offer?

Partial hospitalization may be categorized by function (Worrall-Davies, 2014). Increasingly, they offer a step-up, step-down support and transition between community CAMHS or an inpatient unit. They may provide a nonresidential option for harm reduction, assessing and treating severe and complex patterns of disruptive, delinquent, or offending behaviors. Some day programs offer neuro developmental assessment and treatment with specialist programs of care for prepubertal children with autism, ADHD, speech and language disorders, or neuropsychiatric conditions. Intensive family work may be offered within 5-day-a-week day program interventions with whole families (Multi-family Therapy model (see Chapter 39)). Finally, problem-specific targeted packages of care may be provided within a day program for specific problems such as eating disorders or psychosis.

Day programs have a number of advantages and disadvantages compared to full inpatient admission. Day services work round young people's school or college timetables, can offer family appointments early or late in the day more easily, and individually tailor interventions to young people's needs. School-aged prepubertal children are rarely admitted to inpatient units so day programs are one option for providing detailed observation, assessment, and treatment. The partial “therapeutic milieu facilitates close liaison with families and schools and increases likelihood of learning transferring across settings. However, traveling each day to and from the day program may be tiring and anxiety-provoking for young people and the costs of travel and loss of income from taking time off work to transport their children may be substantial for families.

Young people attend a day unit typically between 8 and 12 hours up to 5 days a week. Traditionally, programs were timetabled rigidly but nowadays they are usually individually tailored, with young people having opportunities to attend their own school, undergo specialized assessments or individual and family therapy sessions. Therapeutic alliance and milieu are as important as in the inpatient setting as they influence outcomes (Hougaard, 1994; Grizenko, 1997; Green *et al.*, 2001; Green *et al.*, 2007). Robust supervision is needed at individual and group level to hold tight care boundaries, otherwise the staff team may mirror dysfunctional family relationships or parenting difficulties. Policies and procedures must be in place to safely manage aggression, bullying, self-harm or harm to others, and absconding. As in inpatient units, staff must be trained in

de-escalation and restraint techniques. Treatment goals should be specific, measurable, and achievable, yet flexible so that they can evolve during treatment. There should be a multiprofessional team plus a core nursing team. Child and adolescent psychiatrists, social workers, clinical child psychologists, speech and language therapists, occupational therapists, physiotherapists, family therapists, child psychotherapists, and teachers all have important roles. The most popular team model is staff working generically, with a flat hierarchy, with task-focused “mini teams” rather than staff working solely within their professional discipline role (Worrall-Davies, in press).

The wide range of partial hospitalization programs makes effectiveness studies difficult to interpret. Furthermore, the necessary evolution of day programs to align with intensive and changing use of inpatient provision of developing community means that efficacy research may not now be as relevant. Recent research has focused on day programs for specific disorders, with mixed findings. The multiple family day treatment model shows promising results with significant symptomatic improvement, low drop-out rates and high family satisfaction with the treatment model (Rockwell *et al.*, 2011). Martin *et al.* (2013) showed significant reduction in behavioral problems in preschoolers who had failed to respond to evidence-based outpatient treatment (see Chapter 65). The classic Grizenko (1997) study also suggested that day programs for prepubertal children with conduct disorder led to significantly more improvements in behavior, self-esteem, and self-reported mood, compared to those on a waiting list, both at discharge and at 6-month follow-up. Poor parental engagement with treatment predicted further required input from social or health services. One study suggests that a day program for substance abuse in adolescents is as effective as hospitalization in terms of treatment completion rates, reductions in substance use and behavior difficulties, and improved psychosocial functioning (Cornwall and Blood, 1998).

Inpatient services

Historical background and trends

Child and adolescent inpatient services have developed from two broadly differing theoretical concepts: “therapeutic milieu,” which aims at effecting personality and behavior change (Bettelheim, 1955; Kennard, 1983), and a bio-psychosocial model (Cameron, 1949), using a comprehensive approach to assessment and treatment often based in a hospital type setting. Today many facets of these models are incorporated into smaller units with a modified ethos or therapeutic milieu alongside more individual psychosocial and medical treatments. While there was a steady expansion of such services particularly in the 1960s and 1970s, more recently there has been a dramatic change in the delivery of inpatient care. In the United States, as elsewhere, there has been a reduction in the length of stay, a greater number of prior admissions, and a greater severity of those admitted, as judged by the level of general functioning (Meagher *et al.*, 2012). In Germany between 2000 and 2007, inpatient admission

rates for children and adolescents increased by 38.1% overall, but with striking variations—conduct disorders rose by 18.1%, hyperkinetic disorder by 111.3%, and both considerably less than depressive disorders 219.6% (Holtmann *et al.*, 2010). In the United States, psychiatric discharges between 1996 and 2007 also increased but more for children (180%) than for adolescents (141%), whereas there was very little change reported for adults (108%) (Blader, 2011). Alongside this, there has been a change in the pattern of diagnoses with a large increase in the United States in admissions of those with early-onset bipolar disorder (see Chapter 62) (Blader and Carlson, 2007; Meagher *et al.*, 2012), which has been reflected to a lesser extent in Germany (Holtmann *et al.*, 2010), but not in the United Kingdom (James, 2010). Moreover, there have been considerable changes in the pattern of clinical care as demonstrated, for instance, by the increased use of antipsychotic medication within the United States only 11.4% receiving antipsychotics on discharge in 1991 compared to 46.7% in 2008 (Meagher *et al.*, 2012). This does not appear to be linked to greater rates of psychosis, but may reflect use of antipsychotics for mood stabilization and possible control of aggression.

There is a steep rise in hospital admissions in the teenage years from 0.2/1000 at 10 years to 2.2/1000 per year at 19 years (James, 2010). These findings alongside the recognition of higher rates of psychiatric disorder in adolescence (Costello *et al.*, 2011) and an increase in the rates of emotional disorders in the 1990s (Maughan *et al.*, 2008), led to a realization of an under-provision of inpatient services in United Kingdom. In 1999, there were 80 adolescent psychiatric units in England and Wales providing 900 beds; this inpatient provision increased by 33% to 1128 beds by 2006 (O’Herlihy *et al.*, 2007). Previously, up to a third of all adolescents in England were admitted to adult wards (James, 2010) or to pediatric wards, half of which were thought to be inappropriate (Worrall *et al.*, 2004).

Types of unit

Inpatient units are general or specialized by function. A major division of inpatient psychiatric services is based upon age and differing developmental needs, particularly those between prepubertal and postpubertal children and adolescents. Child units, often have a greater involvement of parents and family, including in some case the provision to stay, which reflects the finding that compared to adolescents, younger children tend to come from families with higher rates of psychosocial problems (Rice *et al.*, 2002). Adolescence marks a transition for the individual and socially, with the greater influence of peers, and change in schooling and the possibility of leaving home. Such a large transitional period means in practice that general adolescent units often have an informal distinction between the older adolescents (over 16 years) and younger adolescents.

In some countries, particularly those in Scandinavia and Northern Europe, child psychiatric units with an emphasis upon family and parental involvement continue to flourish. Recent surveys in the United States (Blader, 2011) point to a

substantial increase in the use of child psychiatric beds, while in the United Kingdom the number of child psychiatric units has decreased substantially (O'Herlihy *et al.*, 2003). The latter may reflect not only the increased provision of community child and adolescent psychiatric services (CAMHS), but also a reluctance to separate children from families.

There are specialized inpatient services for eating disorders. The need for this specialized service may reflect parental or indeed adolescent demands. However, while there is accumulating evidence for better outcomes for eating disorders with specialized community eating disorder services (Gowers *et al.*, 2010), there is no such evidence for an advantage for dedicated adolescent eating disorder units.

Adolescent intensive care units for violent and or persistently disruptive behaviors, as well as serious self-harming behaviors and persistent suicide attempts, are organized on a supra-regional level. While many modern adolescent units may incorporate purpose built intensive care suites, longer-term intensive care is best provided in purposebuilt units where security can be more easily maintained and where there is access to adequate resources including sports facilities. Patients admitted to such units must be under the Mental Health Act or other statutory provisions (see Chapter 19). Severely disturbed adolescents or those who have committed offenses in the context of mental illness may be referred to adolescent forensic inpatient services (see Chapter 49).

Children and adolescents with mild to moderate intellectual disabilities can usually be catered for in general inpatient units with consultation from learning disability services and by employing dually trained staff. Those with severe intellectual disabilities require separate provision because of the specialized needs and communication difficulties (see Chapter 54). Other specialist units include services for children and adolescents with autism.

How are young people admitted to an inpatient unit?

Inpatient beds are a scarce and costly resource, and therefore preadmission assessment is often considered as a crucial filtering mechanism. In one study of an Irish adolescent unit (Wilson *et al.*, 2012), 46% of referrals were admitted. Depression and suicidality were the most common reasons for referral. While a majority of admissions occurred within 5 days of referral a significant minority were not admitted until over 20 days after referral. Referrers, however, value the possibility of urgent admissions, and it is possible for a service to be configured to accept urgent referrals (Corrigall & Mitchell, 2002), provided there are good community links.

Types of admission

Emergency

Emergency psychiatric admission is required for a range of conditions, particularly serious suicide risk, risk of harm to others associated with mental illness, acute florid psychosis,

and eating disorders with physical complications among others. Accepting emergencies on a 24 hour basis seven days per week, has only been widely accepted practice in the United Kingdom since 2004 (DOH, 2004), previously one third of all adolescent admissions were admitted in adult wards (James, 2010). In order to ensure the necessary availability of an emergency bed, a well integrated community service, including a psychiatric crisis team with in-reach is necessary.

Planned and respite admissions

Referrals should not be delayed: a well-timed intensive treatment may prevent further deterioration (Green & Worrall-Davies, 2008). Brief respite admissions can also be useful in certain situations where the aim is to maintain an ill child or adolescent in the community as far as possible and to help support a family through a difficult period, particularly those families with a child with learning impairment and behavioral problems. The concern that these types of admissions can engender dependency and undermine a family's ability to cope can be over-played.

Reasons for admission and characteristics of who is admitted

The reasons for admission generally fall into a number of broad categories (Box 50.1).

Among a nationwide birth cohort of Finnish children, 6.2% of males and 4.1% of females between the ages 13 and 24 were admitted to hospital for a primary psychiatric reason. The combination of conduct and emotional symptoms was the strongest predictor for admission in both sexes (Gyllenberg *et al.*, 2010). Admission practices vary between countries, and in England the admission rate (2.2/1000 population at age 19 years) is lower, with schizophrenia, affective disorders, neurotic disorders, and eating disorders being the mostly frequent diagnoses (James, 2010). Eating disorders represent a major use of beds as the length of stay is longer.

It is clear, however, that besides psychiatric illness, social factors play a significant role in who is admitted (Kylmanen *et al.*, 2010). Children in the welfare system are overrepresented in child and adolescent psychiatric units (Laukkanen *et al.*, 2013), reflecting the high rates of psychiatric morbidity in this population (McCann *et al.*, 1996). Indeed, alongside any principal psychiatric problem, adolescent inpatients suffer a multitude of difficulties including educational and social difficulties (Tonge *et al.*, 2008). A high level of family dysfunction is common, and many but not all studies report parental personality or psychological disturbance (Tonge *et al.*, 2008). Not surprisingly then, given the multiple problems that adolescent inpatients suffer, treatment that focuses on only some of these factors is likely to have limited effectiveness.

Assessment

Unfortunately, even in inpatient services standardized assessments of psychopathology are not routinely undertaken.

Box 50.1 Indications for inpatient hospital admission.

To manage risk of self-harm and suicide, violence and harm to others, and medical complications associated with eating disorders.

When psychiatric symptomatology is escalating despite the most intensive outpatient treatment available.

The need for detailed assessment in complex cases where the formulation is unclear.

Assessment or treatment away from the family. This has become less of an indication with family therapy becoming more available to assess the family *in situ*.

For controlled trials of specific interventions and drug regimes (i.e., starting clozapine) and coordination of complex physical investigations such as electroencephalography (EEG) and magnetic resonance imaging (MRI).

This has led to the systematic under-reporting and, therefore, treatment of various disorders such as post traumatic stress disorder (PTSD) (Havens *et al.*, 2012). In one study (Lauth *et al.*, 2008), the introduction of standardized semi-structured instruments such as the Kiddie-Schedule for Affective Disorders and Schizophrenia (K-SADS) (Kaufman *et al.*, 1997) led to the increasing recognition of several main diagnostic categories (depressive, anxiety, bipolar, and disruptive disorders), suggesting that those disorders were likely underreported.

Therapeutic function

Inpatient care encompasses a multitude of functions, including the provision of a broad range of evidence-based therapies such as pharmacotherapy, cognitive behavioral therapy, family therapy, supportive individual counseling, and possibly art and music therapy. There is no evidence that these treatments *per se* are more effectively delivered in an inpatient setting; however, there is a belief that with more intensity and consistency these treatments can be more effective.

Inpatient treatment is not just “residential” care with the provision of on-site therapies. A unit will have its own “milieu or ethos” with some specifically designed, such as behavioral units or those adopting family therapy or indeed psychodynamic approaches. Core elements for “milieu therapy” are consistency, boundaries, limit setting, role modeling led by staff, as well as open group forms for exploration and discussion of day-to-day emotional and psychological issues as they arise. A crucial component of inpatient care is physical and psychological containment (Bion, 1962). Patients will often be admitted following the breakdown of social relationships and appear in a distressed, unsettled, and fragmentary psychological state. The act of physical containment, alongside psychological support with boundaries appears essential to help settle the disorganized and sometimes suicidal patient.

Although difficult to define, the therapeutic “milieu” is often seen by staff as a crucial aspect of the functioning of the unit; it is the setting where multiple split transferences and transference reactions are worked through; that is, relationship patterns are re-enacted and often re-played within staff groups, which can then provide a focus for intervention (Pestalozzi *et al.*, 1998). In order to maintain a therapeutic milieu, it is essential that there is good communication among staff, alongside the ability to be able to reflect not only on the day-to-day business but also the emotional aspects of the work. A coherent therapeutic culture

has been shown to be related to therapeutic outcome (Pfeiffer & Strzelecki, 1990; Green *et al.*, 2007).

Behavioral management

Complex behavioral regimes can be implemented within an inpatient service to underpin a psychological treatment program for a variety of disorders such as obsessive-compulsive disorders (OCDs). However one of the main indications for the use of behavioral regimes is to treat aggression (Dean *et al.*, 2007). Physical aggression during admission is common, occurring in one study in up to 23% of inpatients (Dean *et al.*, 2008). Factors that predict persistent physical aggression include a history of aggression and use of medication at presentation. Persistent aggression is also associated with an increased length of stay, but not necessarily a worse outcome. Broad-based behavioral management programs lead to a reduction in aggression (Dean *et al.*, 2010) emphasizing the importance of an organizational approach to behavioral management. Among inpatient staff exposure to aggression is common—occurring in over 84% in one study (Dean *et al.*, 2010). The impact on staff is considerable with difficulty attending work and other emotional and professional sequelae, highlighting the need for a cohesive staff group and regular training to deal with violence.

Seclusion

Seclusion is defined as the placement of a patient in a specifically designed room in order to de-escalate behaviors, assure physical safety, and achieve behavioral control. Restraint refers to a physical intervention, either through therapeutic holding by a caregiver/staff member, or as in certain countries through mechanical restraining tools. Reasons for seclusion and restraint include threats (73%), agitation (63%), and physical aggression (63%) (Delaney and Fogg, 2005). A recent review showed that the use of both seclusion and restraint are reduced after behavioral interventions or more systematic use of restraint (De Hert *et al.*, 2011) and use of the correct legislation. In some countries, for example, in the United Kingdom, mechanical restraints are very rarely used, while a Finnish study found that mechanical restraint was used in 6.9% of adolescent inpatients (Hottinen *et al.*, 2012).

Restraint in particular can have severe consequences including trauma for the individual, a reactivation of prior traumatic experiences and serious physical side effects, such as asphyxia, aspiration, blunt trauma to the chest, thrombosis, and even death.

One US national study (Nunno *et al.*, 2006) reported 45 fatalities between 1993 and 2003 in child and adolescent psychiatric facilities related to restraints.

In certain cases, aggression or disturbed behavior may be managed by the use of medication. Rapid tranquillization techniques involve the administration of short acting benzodiazepines or antipsychotics intramuscularly or via rapidly absorbed oral preparations. Such procedures are relatively safe provided that there is a clear protocol and regular and frequent physical monitoring by trained staff.

Risk management

The management and reduction of risk of harm to self or others is a crucial function of an inpatient unit. Vital to this process is the detection and quantification of risk. A thorough and detailed history with corroborative evidence is essential. Finely tuned clinical skills can be enhanced in an inpatient setting with a multidisciplinary perspective, which adds an extra dimension—for example, by having both male and female viewpoints. Furthermore, it is possible to assess risk over time, and dynamically, via the interaction with observable stressors within the unit. A major advantage of residential psychiatric care is the possibility of modifying the milieu by various means—varying the level of nursing observations, excluding stressors and gradually re-introducing them.

Clinical skills based upon detailed observation are at the heart of a risk assessment. Routine questionnaires can supplement the risk assessment for self-harm, but cannot replace it. The limited research available indicates that violence toward others, unlike self-directed violence, can be successfully predicted using clinical judgment (Phillips *et al.*, 2012). Semi-structured assessments of violence such as the SAVRY (Structured Assessment of Violence Risk in Youth) have good predictive validity (Singh *et al.*, 2011) and can be recommended.

Does inpatient admission work?

Length of stay

There is trend for shorter admissions but with more complex presentations (Olfson *et al.*, 2005). Shorter admissions have been shown not only to be feasible, but effective. In one study (Swadi & Bobier, 2005), the mean length of admission was 23.7 days for mood disorders, 18.9 days for anxiety disorders, and 46.9 days for major psychoses. Most improvements occurred during the first 3 weeks of admission. Importantly, readmission rates were not elevated. However, longer stays, positive therapeutic alliance and better premorbid family functioning have been found independently to predict better outcome (Green *et al.*, 2007).

Readmission

Readmission occurs in a surprisingly high number of cases—for example, 43% (James *et al.*, 2010). Re-hospitalization is highest during the first 30 days following discharge and remains elevated for 3 months. Medication nonadherence and a history of childhood sexual abuse are associated with readmission (Bobier &

Warwick, 2005). A Danish 10-year follow-up study found that 25% of those re-admitted became “long-term” psychiatric inpatients, particularly those with schizophrenia and affective psychoses (Pedersen & Aarkrog, 2001).

Outcomes and evaluation

The evidence for inpatient care is limited by the fact that as safety is a major driver for use of inpatient services, it is neither feasible nor ethical to conduct randomized controlled trials to evaluate its use. Nevertheless, a meta-analysis of 34 open studies of children and adolescent inpatients highlighted clear clinical improvements for inpatient care (Pfeiffer & Strzelecki, 1990), but poor long-term prognosis has been noted for some early-onset disorders such as psychosis (Healy & Fitzgerald, 2000). A prospective study (Green *et al.*, 2007) found significant and clinically meaningful clinical improvements across all diagnoses, maintained at 1-year follow-up, following an average 16-week admission. The mean cost of admission was £24,100 (UK costs in 2007). Curiously, despite the clinical improvements, which enabled the patients to be subsequently treated within community mental health services (CAMHS), preadmission and postdischarge support costs were similar. This finding for inpatient care contrasts with that from a community study of 56 severely disturbed adolescents in United Kingdom (Clark *et al.*, 2005) whose costs including placement in various residential units amounted to £56,000 per child/adolescent per year—over double that of psychiatric inpatient care with no appreciable change in the level of symptoms or functioning. Direct comparisons may not be possible and while there is evidence pointing clearly to improvements for inpatient psychiatric care, it is evident, nonetheless, that residential care for the severely disturbed children and adolescents is expensive.

Suicide

A prospective study (Kapur *et al.*, 2013) of patients admitted to national health service (NHS) inpatient psychiatric care in England between 1997 and 2008 showed a significant drop ($p < 0.001$) in inpatient suicides from 0.4 to 0.1 per 100,000 population in the 15–24 age range (Kapur, personal communication). Moreover, for all ages, rates fell for the most common suicide methods, particularly suicide by hanging (a 59% reduction). On a unit level, the design of the unit with the removal of ligature points is essential and implementing procedures such as follow-up appointments within 7 days of discharge may contribute to better outcomes.

Cost/benefits

As with all therapies, inpatient care can have side effects. Admission to an inpatient service often involves disruption of family, school, and links with the community. While support and care for the young person can be an important part of the inpatient treatment, patients and families can feel deskilled, possibly because crucial supporting structures within the community

and family are lost and patients can become isolated and dependent on hospital care. Additionally admission can be costly personally with parents paying up to £2000 in travel costs to the unit alone (UK costs 2007) (Green *et al.*, 2007).

Discharge and transition to the community

There is some preliminary evidence from adults that the introduction of care coordination (CPA)—the process of coordinating multidisciplinary professional input with the patient, family, and family GP or physician—results in better care with less psychiatric crisis team input, lower rates of readmission and greater satisfaction for both patients and relatives following discharge (Stewart *et al.*, 2012). Curiously, a US and Canadian study found that while only 50% of discharged adolescents received aftercare, those who did were more likely to be re-admitted (Carlisle *et al.*, 2012). Disappointingly, follow-up research shows that only a proportion of inpatients receive the recommended services upon discharge (Green *et al.*, 2007).

Transition points into and out of an inpatient service and the transition of the older adolescent to adult mental health services are vital points in any care pathway because of the increased risk of disruption in continuity of care, disengagement from services, and possibly poorer clinical outcomes, including the risk of suicide. Some young people, such as those with neurodevelopmental disorders and complex needs, are at a greater risk of falling through the care gap during transition to adult services (Singh, 2009). This has led some to argue for the development of youth community services with an upper age range of 25 years. It would not be envisaged that this would extend to residential facilities with the disparate needs of younger adolescents and adults.

Postdischarge is recognized as a risk period. The death rate within 1 year of discharge from an adolescent inpatient service is six times higher than that in the general population of the same age, although the total number of deaths following discharge from NHS child adolescent psychiatric units in England was low at 120 over a 6-year period (1998–2004) (James, 2010). The suicide rate is highest in the year after inpatient admission with a Korean study showing that the standardized mortality ratio (SMR) among former adolescent inpatients was 7.8 (95% CI 4.7, 12.3) for unnatural causes and for suicide, it was 14.2 (95% CI 7.7, 23.7) (Park *et al.*, 2013). Among the different diagnostic groups, patients with personality disorders, schizophrenia, or affective disorders had the highest risk for suicide.

Summary of some key findings

There is accumulating evidence that intensive community programs, partial hospitalization, and day patient programs are effective, but it is not clear which type of program works best for which young people. More research is needed to delineate this. In the global context, community intensive services may be more achievable in the foreseeable future than inpatient units, for financial, geographical, and resource issues, but again care should be taken before embarking on setting up expensive

services to establish whether they are effective in the settings they are being conducted in.

Moreover, there is evidence that inpatient care can produce substantial clinical improvement in the short and medium term. Readmissions rates are high (30%) and continued clinical improvement is dependent upon aftercare provision. The longer-term outlook for those with major mental illness, particularly psychosis, is poor in a proportion of cases, but evidence from early intervention services with appropriate inpatient care is encouraging (see Chapter 57).

Final conclusions

There has been an expansion of types of intensive services, some focused on certain patient populations or types of therapy and many of which have evidential support. Further work is needed to determine whether integration of these services with inpatient care can improve clinical outcomes, reduce the number of admissions, length of stay, and reduce costs. The move for shorter hospital stays, but with increased complexity (Olfson *et al.*, 2005) will continue to pose considerable clinical demands.

²Child and Youth Mental Health Collaborative, Hospital for Sick Children, Centre for Addiction and Mental Health, Division of Child and Adolescent Psychiatry, University of Toronto, Toronto, ON, Canada

Overview

This chapter will provide a comprehensive review of the clinical presentation, etiology, outcome, risk factors, assessment, and treatment associated with autism spectrum disorder (ASD). The term ASD will be used throughout this chapter (consistent with the newly published DSM-5 diagnostic criteria) to report on findings with respect to autism, Asperger syndrome (AS), or pervasive developmental disorder not otherwise specified (PDDNOS). Systematic reviews and meta-analyses have been employed rather than primary studies, to provide summaries of the literature in as unbiased and as comprehensive a way as possible. If several reviews on a topic were available, the most methodologically rigorous reviews were retained or those that contained the highest quality studies (using PRISMA or Preferred Reporting Items for Systematic Reviews and Meta-Analyses as a guide, see Liberati *et al.*, 2009). Individual studies have been used to highlight areas only when a recent systematic review was not available or to contextualize the information, provide historical background, or highlight emerging trends.

Clinical characteristics of ASD

ASD is the term now widely used to describe a neurodevelopmental disorder characterized by impairments in reciprocal social communication and a tendency to engage in repetitive stereotyped patterns of behaviors, interests, and activities. In common with other neurodevelopmental disorders, ASD arises from atypical brain development. Boys outnumber girls, the core features are typically present in early childhood (but may not always be apparent) and the etiology (as yet incompletely understood) is likely to be multi-factorial (see Chapter 3). The clinical presentation can change over time, often in response to the

demands of the environment or in the presence of co-occurring conditions. Many individuals with ASD have an early history of apparent regression or a period of lack of progress of language, of cognition more generally, or social behavior in the early preschool period. Overall there is a tendency for core behavioral symptoms to improve over time but some behaviors may persist and present a longer term challenge. Affected individuals often have additional problems with independent daily living skills, motor coordination, sensory sensitivities, sleep and eating problems, mental health difficulties, and behaviors that place themselves and others at risk.

The clinical presentation of ASD is remarkably diverse usually with a combination of some delayed/immature behaviors together with the emergence of more unusual behavioral profiles. Some of the earliest social communication symptoms represent difficulties in joint attention, eye contact, lack of social intention to communicate with others, lack of social imitative play and fascination with sensory stimuli. Symptoms change over time, in some cases becoming more obvious (motor stereotypes, lining up of objects, lack of interest in other children and inability to play cooperatively), in other cases becoming more subtle (difficulties in conversation with others, lack of empathy, emergence of intense circumscribed interests, rigid thinking style, problems with reciprocal friendships). Some symptoms of ASD are an exaggeration of delays observed in typical development (lack of useful speech, limited symbolic, and imaginative play skills) whereas other symptoms are quite distinct and are rarely (or only very transiently) observed in the development of typical children (delayed echolalia and neologisms).

Cognitive difficulties are very common in individuals with ASD although their nature can vary dramatically. Some degree of intellectual disability is found in approximately 25–50% of individuals with ASD depending on ascertainment (Matson & Shoemaker, 2009). With the broadening of the diagnostic criteria for ASD, the proportion of individuals with intellectual

disability has declined (Fombonne, 2005) over time. The most common pattern of cognitive profile is poor language and social comprehension but with relative strengths, even “splinter skills” (see Chapters 52 and 53) in visual-spatial abilities (Meyer & Minshew, 2002). Among higher functioning individuals the opposite pattern may also occur, a profile sometimes labeled as a “non verbal learning disability” (Klin *et al.*, 1995; Mayes & Calhoun, 2003). “Hyperlexia,” a remarkable ability to read but with little comprehension of content, is sometimes observed in severely disabled individuals (see Chapter 53).

Children with moderate to severe cognitive impairment at earlier developmental stages in the preschool years often present with little or no speech and poor non verbal communication. They also tend to engage in repetitive play with sensory stimuli and can become quite upset by stimuli from the environment such as the texture of certain clothes, some everyday noises and particular foods. With higher functioning or older individuals, speech and language are often present, grammar and vocabulary may be age appropriate, but there remain pragmatic difficulties in the social use of communication. In addition to the sensory interests, higher functioning children and adolescents with ASD often develop intense circumscribed interests that are observed in typically developing children but are pursued in a solitary, non social, manner.

The history of diagnosis and classification

Many terms have been used to refer to children with these complex neurodevelopmental presentations: autism, infantile autism, childhood schizophrenia, childhood psychosis, ASD, atypical autism. With the publication of DSM-III, autism was clearly differentiated from childhood schizophrenia and other psychoses, the term “pervasive developmental disorders” (PDDs) was first introduced and some standardized, reliable criteria became widely available (American Psychiatric Association, 1980). DSM-IV (American Psychiatric Association, 1994) included several subtypes of PDD: autism, AS, PDDNOS, Rett syndrome, and disintegrative disorder. AS referred to individuals with characteristics of autism but without clinically significant cognitive or language delay. PDDNOS referred to individuals with characteristics of autism but not enough to qualify for a diagnosis of either autism or AS. Rett syndrome was a type of PDD that was characterized by a period of normal development and then a very specific set of signs and symptoms (e.g., hand wringing) with developmental regression. Disintegrative disorder was a subtype of PDD characterized by normal development past 36 months of age at which point the clinical presentation of autism would emerge.

Prior to the publication of DSM-5 (2013), a systematic literature review and some commissioned primary research were conducted by the DSM-5 Neurodevelopmental Disorder Working Group. The group concluded that there was insufficient evidence that the clinical distinctions between autism and the other subcategories could be made reliably (Lord

et al., 2012a) or that these subcategories differed on important variables with respect to etiology, outcome, or response to treatment. As a result, the subcategories have been eliminated and replaced with the single diagnosis of “ASD” with the opportunity to indicate any coexisting diagnoses [epilepsy, Attention Deficit Hyperactivity Disorder (ADHD), social anxiety disorder], or accompanying intellectual disability or language disorder. DSM-5 has also revised the diagnostic criteria for ASD replacing a triad of impairments with two behavioral domains—social communication and repetitive stereotyped behaviors. Although delays in language acquisition are common in ASD, they are nonspecific and so have been removed from the diagnostic criteria. Each domain includes different groups of symptoms or sub-domains (see Figure 51.1) and can be represented dimensionally depending on the need for intervention and support.

DSM-5 includes stereotyped and repetitive speech within the restricted/repetitive behaviors domain and for the first time sensory reactivity to aspects of the individual’s environment has also been included. For an individual to meet criteria for a DSM-5 diagnosis of ASD, evidence of symptoms in all three of the social-communication sub-domains and any two (or more) of the four restricted and repetitive behavior sub-domains is required (see Figure 51.1). For individuals who meet criteria for impaired Social Communication in the absence of restricted and repetitive behaviors, a new diagnostic category of Social Communication Disorder has been included in DSM-5 (see Chapter 52).

The changes published in DSM-5 have generated considerable controversy. Some advocates, clinicians, and researchers have expressed concerns that the revised DSM-5 criteria might under-diagnose individuals who would previously have received an ICD-10/DSM-IV diagnosis of (high functioning) autism or AS (McPartland *et al.*, 2012). To date, recently published data do not support this concern (Frazier *et al.*, 2012; Huerta *et al.*, 2012; Kent *et al.*, 2013). Indeed there is evidence that in addition to equivalent levels of sensitivity, reported higher estimates of specificity suggest an improvement in overall diagnostic accuracy.

Epidemiology

Prevalence rates

Up until the 1980s autism was considered to be a rare disorder affecting approximately 4 per 10,000 children (Fombonne, 2005). With the publication of DSM-III, reported prevalence rates of ASD have steadily risen both in the developed and developing world. Systematic reviews (Fombonne, 2005; Williams *et al.*, 2006; Elsabbagh *et al.*, 2012) suggest a prevalence rate of 1 per 100 in developed countries with a lower rate in developing countries. Very high rates (3%) have been reported in South Korea and Japan (Williams *et al.*, 2006; Kim *et al.*, 2011). These findings will need replication as cultural or measurement issues may have contributed (Elsabbagh *et al.*, 2012).

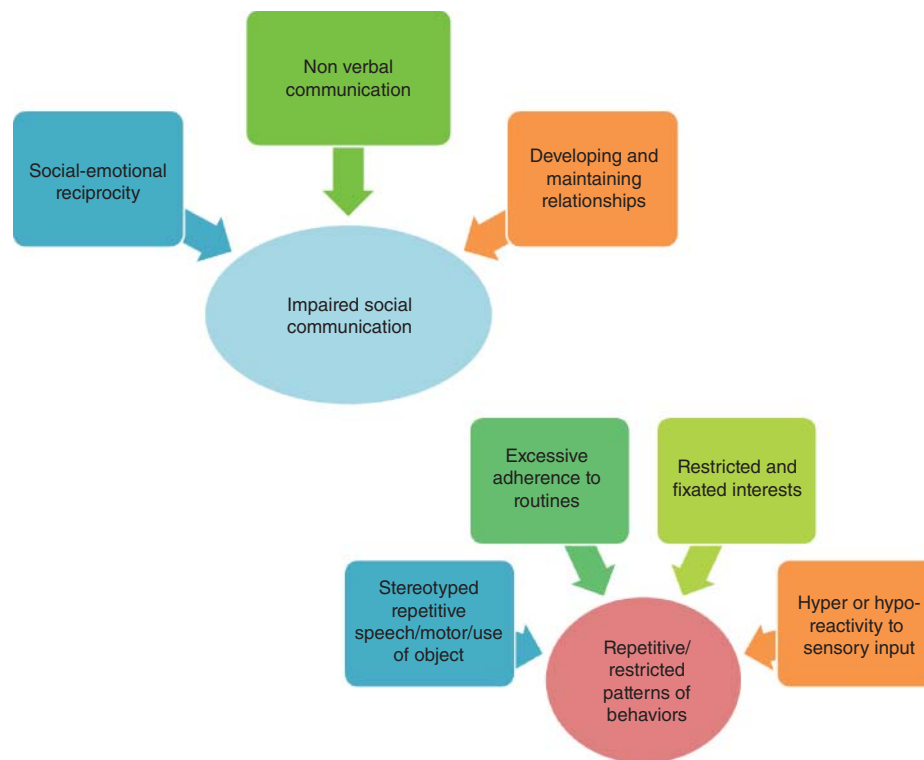

Figure 51.1 The two domains in the DSM-5 1. social-communication and 2. repetitive and restricted patterns of behaviors are shown in the circles. The sub-domains that make up the domains are shown in the squares. *Source:* Reproduced with permission of Rachel Kent and Sarah Carrington, Wales Autism Research Centre, Cardiff University.

There has certainly been an increase in public awareness of ASD, the diagnostic criteria have been broadened and clinicians have a much better understanding of the clinical presentation of ASD in very young children, in those who are higher functioning as well as in adolescents and adults. Moreover, it is true that a diagnosis of ASD can now be made in conjunction with other co-occurring conditions such as a mental health disorder, ADHD, Down syndrome, or the fragile X chromosomal anomaly, a practice that was discouraged within the previous classification systems. In the USA, a rapid increase in the number of children receiving a diagnosis occurred once legislation for special schooling was introduced for autistic children (Gurney *et al.*, 2003). There is also some evidence of “diagnostic substitution” occurring, that is, the prevalence of “mental retardation” is decreasing at roughly the same rate as the prevalence of ASD has been increasing (King & Bearman, 2009). The recent estimates provided by the US Center for Disease Control show considerable variation between states probably as a consequence of significant variation in access to diagnostic services (Center for Disease Control, 2012). Even given these caveats, it is still unclear whether there has been a true increase in prevalence of ASD in recent years.

Although it is well recognized that boys outnumber girls with the disorder, the exact sex ratio is uncertain. Clinic samples tend to report higher ratios (4–6 to 1) of boys versus girls while community samples tend to report lower ratios (2–3 to 1)

(Fombonne, 2005). This has prompted discussion as to whether ASD is under recognized in higher functioning females. It is generally understood that girls with a diagnosis of ASD tend to have lower IQ, more cognitive impairment and fewer repetitive stereotyped behaviors (Amiet *et al.*, 2008). While there is no clear understanding of the male bias in prevalence and difference in presentation, it is also true for other neurodevelopmental disorders and so an ASD-specific explanation may not be required (see Chapter 3).

Population screening

Parents often become concerned about the development of their children at 12–18 months of age but children most commonly do not receive a diagnosis until 4 or 5 years of age (Zwaigenbaum *et al.*, 2009). This represents a significant time lag in access to ASD specific interventions and management of any identified co-occurring problems. These now well replicated findings have given rise to the question as to whether universal screening programmes should be instituted to perhaps reduce the time to diagnosis. However, the American Academy of Pediatrics (AAP) and the UK National Screening Committee do not recommend universal screening. The AAP does suggest that surveillance for ASD should take place at well baby visits at 6, 12, 18, and 24 months (Johnson & Myers, 2007) despite the lack of screening tools with good psychometric properties. It is also true that no randomized control trial of a combined screening

and treatment intervention has been conducted to determine whether early screening and earlier age of diagnosis does in fact lead to better long-term outcomes (Al-Qabandi *et al.*, 2011).

Other screening tools have been developed with the aim to be more diagnostic-specific; that is, to have both high sensitivity and specificity. A systematic review by Norris and Lecavalier (2010) examined the sensitivity and specificity of several parent-rated questionnaires and concluded that no screening instrument currently available has sufficient sensitivity and specificity to be used as a diagnostic instrument.

Economic cost

Knapp *et al.* (2009) suggested that the annual societal cost associated with caring for children with ASD in the United Kingdom is approximately £2.7 billion and nearer £25 billion for adults. In the United States, health care costs per individual with ASD have risen by 20.4% from \$4965 in 2000 to \$5979 in 2004 (Leslie & Martin, 2007). These figures indicate that among all mental disorders, health care spending in the United States is the highest for individuals with ASD, who had higher physician and outpatient visits as well as greater prescribed medication use when compared to the non ASD paediatric population (Liptak *et al.*, 2006).

Cultural factors

The prevalence of ASD is reported to be lower in countries outside North America, Europe, Japan, and South Korea (Zaroff & Uhm, 2012). This may be attributed to methodological factors which can influence the nature of detection, diagnosis and treatment of ASD (Brown & Rogers, 2003). Currently, there are limited data on the difference in ASD prevalence among various ethnicities and methodological issues have made it difficult to decipher the role of culturally specific influences (see Chapter 16). Zaroff and Uhm (2012) have reported higher rates of ASD among white Americans compared to Hispanic individuals. Likewise, according to Bernier *et al.* (2010), white Americans receive a diagnosis approximately a year and a half before African-American children and two and a half years before Latino children.

Cognitive and emotional processes

Identifying the cognitive phenotype or profile of ASD is likely to play a critical role in increasing understanding of the underlying brain systems and structures involved in this phenotypically heterogeneous disorder. Understanding these processes may potentially enhance our understanding of how autistic behaviors arise and of the lived “autistic experience” (Charman *et al.*, 2011). Two neuro cognitive models (Theory of Mind (ToM) (Baron-Cohen *et al.*, 1985, 1995) and Executive Dysfunction (Turner, 1999a; Ozonoff & Strayer, 2001) appear related to aspects of the diagnostic criteria for autism/ASD. Subsequent cognitive theories such as Weak Central Coherence (WCC) (Frith, 1989; Happé & Frith, 2006), enhanced perceptual functioning (Motttron *et al.*,

2006), reduced generalization and enhanced discrimination (Plaisted, 2001) and hyper-systemization (Baron-Cohen *et al.*, 2005) have focussed on different aspects of cognitive functioning. Taking into account the heterogeneity of ASD and the high rates of co-occurring conditions, it is perhaps not surprising that none of these models has provided a satisfactory unitary account of all domains of the ASD behavioral phenotype. Each profile/model has, however, provided useful insights into some of the difficulties experienced by individuals with ASD (see Chapters 3 and 31).

The “ToM” deficit focuses on aspects of the social communication impairments and the inability to impute mental states either to oneself or to others (Baron-Cohen *et al.*, 1985, 1995). The early studies using the false belief task (FBT) identified that individuals with ASD showed deficits in tasks involving mentalizing. However it is now clear that individuals with ASD of higher verbal ability are capable of completing the FBT. A different approach has been used to reconceptualize the ToM deficit as an innate inability to find social meaning in events (Klin *et al.*, 2003)—a problem often reported in individuals with ASD.

Executive function (EF) refers to a range of skills including working memory, capacity to plan, the initiation and monitoring of one’s actions, impulse control, capacity to shift set, and inhibition of pre-potent responses. These functions are usually understood to involve the prefrontal cortex (Ozonoff *et al.*, 1991). Executive dysfunction refers to difficulties in any or all of these functions and can be a feature of many clinical conditions. It is unlikely, therefore, that there is a diagnosis specific profile of executive dysfunction in ASD (see Chapter 3). Moreover, findings suggest that the executive control laboratory experimental tasks may capture atypical cognition in ASD rather than EF deficits. Furthermore, inconsistencies have been identified between human administered and computer administered tasks. For ASD subjects, reported impairments in EF may be a consequence of ability rather than of autism (Hill, 2004; Russo *et al.*, 2007 Kenworthy *et al.*, 2008; Sanders *et al.*, 2008; Geurts *et al.*, 2009). However, as with the ToM deficit, these difficulties are reported as common in ASD and may help our understanding of some of the behavioral features of ASD including a lack of ability to generalize learned responses across settings and the presence of repetitive and stereotyped behaviors (Turner, 1999b; Pellicano and Stears, 2011).

The WCC Theory was formulated by Frith (1989) arguing that individuals with autism demonstrated a local processing bias (and thus a WCC). This cognitive style could explain the enhanced performance of children with autism on tasks such as the Embedded Figures Task (EFT) and could account for “islets of ability” such as the superior performance on the Block Design test (Frith & Happé, 1994) that are commonly observed in individuals with ASD. These perceptual abilities might also account for the extreme distress experienced by some children with ASD at small changes in the environment. Research findings (Happé & Frith, 2006) have shown support

for this cognitive style across different abilities but have also highlighted inconsistencies. For instance WCC appeared to be a characteristic only of a subset of individuals with ASD, can occur in children with other disorders, and individuals with autism were shown to be able to process at a global level if they are instructed to do so (Plaisted *et al.*, 1999). Happé and Frith (2006) revised the concept of WCC placing increased emphasis on possible superiority of local/detail-focussed processing over more holistic processing which can be overridden with specific situational demands to encourage processing at a global level. This conceptualization is certainly consistent with some of the imaging findings in ASD (see Chapters 11 and 31).

Longitudinal outcome

Diagnostic stability and adult outcome studies

Woolfenden *et al.* (2012) conducted a systematic review of 23 longitudinal studies examining diagnostic stability of children diagnosed with ASD. Using DSM-IV diagnostic criteria, although autistic disorder was found to be a stable diagnosis there was a small percentage of individuals, approximately 15%, in whom the child's symptom profile at follow-up no longer met the diagnostic criteria for an autistic disorder. The pattern of stability was much more variable for those with AS and PDDNOS. Within these two groups only a minority retained their initial diagnosis at follow-up. For some, their profile of skills and difficulties no longer met the diagnostic criteria for any PDD, while for others the diagnostic profile at follow-up was more in keeping with a diagnosis of autistic disorder.

There are surprisingly few prospective longitudinal studies following children with ASD from early childhood to adulthood. It is fortunate that the studies that have been conducted use a common outcome tool (Howlin *et al.*, 2004) that classifies individuals as having an outcome ranging from "very good" to "very poor" (Billstedt *et al.*, 2005; Eaves & Ho, 2008; Farley *et al.*, 2009; Howlin, 2013). These studies report wide variation in outcome with between <5% and 25% having a very good outcome (Levy & Perry, 2011). Overall for many individuals, there is a gradual reduction in autistic symptoms and an improvement in adaptive abilities over time but it is the *variability* in individual outcomes that is most striking. The major predictors of better long-term outcome appear to be higher IQ and the presence of useful speech before 5 years of age, but even within that higher functioning group there is considerable variability (Billstedt *et al.*, 2007; Levy & Perry, 2011). The origin of this variability remains obscure.

Although there is a general trend of improvement, new challenges often appear especially at times of change and transition such as changing educational setting, becoming an adolescent and moving on to young adulthood. Some studies report a deterioration in functioning during adolescence. This may coincide with the development of epilepsy or onset of comorbid psychiatric disorders including anxiety and mood disorders.

Individuals with ASD appear to have higher rates than the general population of ADHD, mood and anxiety disorders, Obsessive Compulsive Disorder (OCD), Tourette's Syndrome, Disruptive Behavior Disorders/Oppositional Defiant Disorder and behaviors that challenge (Matson & Nebel-Schwalm, 2007; Shattuck *et al.*, 2007; Simonoff *et al.*, 2008, 2012; Szatmari & McConnell, 2011; Van Steensel *et al.*, 2011). ADHD and anxiety disorders are probably the two most common comorbid disorders (Szatmari & McConnell, 2011). The specific risk factors and mechanisms associated with the occurrence of these co-occurring disorders have not been determined.

Recent studies have reported the developmental trajectories of adolescents with ASD across the transition into young adulthood (Taylor, 2009). The exit from school can be extremely stressful and lead to a slowing down of overall progress. The issue of transition into adulthood is a serious concern for many individuals with ASD and their families as the lack of resources in adult mental health, social care, and developmental disability provision becomes apparent (Seltzer *et al.*, 2003, 2004; Farley *et al.*, 2009).

There are few data on mortality rates in individuals with ASD but it does appear that mortality is slightly increased (Woolfenden *et al.*, 2012), perhaps a reflection of medical events such as status epilepticus or accidental death associated with epilepsy. This emphasizes the importance of monitoring for seizures during adolescence as a potentially preventable cause of mortality.

Risk factors and possible aetiologic mechanisms

Genetic studies

It was with the publication of the first twin study by Folstein and Rutter (1977) that the importance of genetic factors in ASD was appreciated. Early studies reported that the sibling recurrence risk (the risk that a sibling of a child with autism would also carry this diagnosis) was extremely low, around 2–3% (Szatmari *et al.*, 1998). More recent family studies have used the baby sibling design, in which infant siblings of an older child with autism are followed from birth. A combined analysis of many different samples reported that the sibling recurrence risk is around 19% in siblings followed prospectively from birth (Ozonoff *et al.*, 2011). This much larger estimate probably reflects broader diagnostic criteria for ASD and a longitudinal design (see Chapter 24).

A number of twin and family studies have also reported that sub-threshold autistic like traits occur in the relatives of individuals with ASD more commonly than expected. These traits, termed the "broader autism phenotype" (BAP), are said to occur in upwards of 20% of the parents and siblings of individuals with ASD compared to 5–10% in control families (Le Couteur *et al.*, 1996; Sucksmith *et al.*, 2011). These traits refer to qualitatively similar difficulties in social communication, rigidity, and circumscribed interests but are associated with

less impairment and disability compared to individuals with an ASD diagnosis.

A number of recent reviews (Ronald & Hoekstra, 2011; Posthuma & Polderman, 2013) have confirmed that more recent twin studies support a strong genetic contribution to the etiology of ASD although the estimates of heritability vary. These high heritability estimates have encouraged researchers to look for autism susceptibility genes. Systematic reviews of the different linkage studies have identified replication of linkage regions across the genome where susceptibility genes may exist (Trikalinos *et al.*, 2005; Li *et al.*, 2012). However, fine mapping under those linkage peaks has not detected definite evidence of genetic variants that cause ASD. Genome Wide Association Studies (GWAS) have also been considered a fruitful approach to identify the underlying genetic causes of ASD, but generally speaking the majority of reported genetic variants have not been replicated across different studies (Sullivan *et al.*, 2012).

GWAS have relied on the assumption that the genetic variants that cause ASD are relatively common in the population. However, there is an argument that rare genetic variants are more likely to cause most cases of ASD than common variants. ASD has a profound effect on fertility as people with ASD generally do not reproduce and so the likelihood that common variants could act as susceptibility genes with high penetrance is low (Malhotra & Sebat, 2012).

It has been recognized for many years that rare single gene disorders such as fragile X, tuberous sclerosis, neurofibromatosis, and certain chromosomal abnormalities are important examples of rare genetic variants associated with ASD. There are many Mendelian disorders (most often associated with intellectual disability) that are associated with ASD (Abrahams & Geschwind, 2008; Betancur, 2011). In studies with large sample sizes, chromosomal abnormalities at many different loci have also been reported to be associated with ASD. The most common abnormalities involve chromosome 7q and 15q but given that there are so many brain expressed genes it is not surprising that ASD can be associated with abnormalities at many different loci. The well-replicated finding that between 5% and 15% of individuals with ASD have either a single gene disorder or a chromosomal abnormality (Devlin & Scherer, 2012) highlights the importance of general medical screening and genetic testing as part of the diagnostic assessment.

Copy number variants (CNVs) are another important example of genetic variants (see Chapter 24). Rare *de novo* CNVs have now been reported in an ever-increasing proportion of individuals with ASD. Each occurs in less than 1% of the population of individuals with ASD, but cumulatively may account for 15–20% of the population of individuals with ASD (Devlin & Scherer, 2012). These CNVs tend to be rather large and so are likely to disrupt coding regions of one or more genes.

Many genes carrying CNVs have been reported in ASD. These genes appear to be involved in synaptic plasticity, neuronal development, and chromatin re-modelling. In other words, many of the genes associated with ASD (and with intellectual

disability, schizophrenia, ADHD and epilepsy) are involved in maintaining the integrity of the synapse and DNA structure within neurons (see Chapter 24). This provides some evidence that the genes involved in ASD are likely to be part of one or more common pathways. Another outcome of the discovery of CNVs has been the ability to test the function of these genes in animal models where specific loci are “knocked out” or disrupted in some way. This work may lead to the development of new treatment approaches (Crawley, 2012).

Environmental risk factors

The study of environmental risk factors has attracted considerable attention in recent years, especially in the context of gene–environment interactions, but for the most part it has been difficult to identify risk factors that are replicated across studies or to understand the chain of causation that might link a potential risk factor to ASD (see Chapter 23). Many different risk factors have been studied but available systematic reviews have focused on pre- peri- and post natal obstetric complications, exposure to toxins, migration, and parental age.

Pre-, peri-, and post natal complications

Systematic reviews and meta-analyses have addressed the question of whether children with ASD are more likely to be exposed to obstetric complications than the general population (Kolevzon *et al.*, 2007; Gardener *et al.*, 2009; Guinchat *et al.*, 2012). Many obstetric complications have been studied as possibly associated with autism. These include extreme prematurity, hypoxia, bleeding during pregnancy, Caesarean delivery, maternal gestational diabetes, medication use (valproate), breech presentation and neonatal encephalopathy (National Institute for Health and Care Excellence (NICE), 2011). The odds ratios associated with these risk factors tend to be relatively low (less than 3.0) but there is some consistency across the systematic reviews. Using retrospective case-control designs it is still unclear whether the obstetric complications are a true risk factor, represent an outcome associated with a primary abnormality in the fetus, or reflect a methodological artefact.

Environmental chemicals and teratogens, ethnic status and parental age

A systematic review by De Cook *et al.* (2012) evaluated the role of endocrine disruptors such as bisphenol A (BPA), phthalates, pesticides and hazardous air pollutants (HAPs) in the environment. The authors concluded that there was possibly a positive relationship between exposure to pesticides in the atmosphere and the prevalence of ASD in that region. However, these studies are based on ecological data and are far from providing proof of causality.

Two systematic reviews (Landrigan, 2010; Dufour-Rainfray *et al.*, 2011) discussed the role of maternal use of thalidomide, valproic acid (VPA), ethanol misoprostal, and chlorpyrifos during pregnancy. It appears that individuals who were exposed to thalidomide prenatally were 50 times more likely to have

a child with ASD than mothers in the general population (Dufour-Rainfray *et al.*, 2011). VPA, an anti-epileptic drug, is another teratogen and has been shown to increase the prevalence among those exposed by 8–18 times compared to the general population (Dufour-Rainfray *et al.*, 2011). There are mixed results with respect to alcohol intake and autism so no conclusion is possible.

According to Gardener *et al.* (2009), maternal birth abroad is associated with a 28% increased risk, while in Nordic countries the risk associated with immigrant mothers increases to a statistically significant 58%. Dealberto (2011) investigated the association between the prevalence of autism and maternal immigrant status or ethnic origin as it relates to vitamin D insufficiency. Out of the four studies that were reviewed, three reported an increased risk of autism in children from mothers with a different ethnic origin, with one study indicating a greater risk for immigrant mothers from East Asia.

Four reviews (Kolevzon *et al.*, 2007; Gardener *et al.*, 2009; Hultman *et al.*, 2010; Hamlyn *et al.*, 2012) suggest that both advanced maternal and paternal age are risk factors for autism, with paternal age perhaps playing a more significant role. According to Hultman *et al.* (2010) fathers over the age of 50 have the greatest risk of having an offspring with autism compared to fathers below 30 years of age. Gardener *et al.* (2009) estimated that mothers over the age of 30 had a 27% increased risk. Possible biological mechanisms involved in maternal ageing may increase risk for chromosomal imbalances which in turn increases risk for ASD. Older fathers, on the other hand, may experience a higher frequency of point mutations, gene imprinting effects, genetic changes in sperm cells, de novo CNVs, or epigenetic influences that may increase the risk of autism in their offspring (Shelton *et al.*, 2010; Sandin *et al.*, 2012).

Neurotransmitters and neuromodulators

Neurotransmitters have been studied in ASD for over 50 years (see Chapter 3). The most consistent and well-replicated finding has been that 25–50% of children and adolescents with autism have elevated serotonin levels in blood and platelets (McDougle *et al.*, 2005; Lam *et al.*, 2006). However, the relationship between serotonin measured in blood and serotonergic neurotransmission is not well understood. Several studies have reported no difference in CSF levels of 5HIAA (a metabolite of serotonin) between individuals with autism and non autism control groups (Lam *et al.*, 2006). Other researchers have identified differences in whole brain serotonin synthesis capacity in children with autism compared to age-matched non autistic children and also asymmetries of cortical serotonin synthesis in children with autism using neuroimaging (Chugani *et al.*, 1999; Chandana *et al.*, 2005).

Other neurotransmitter systems that have been studied include dopamine, norepinephrine, acetylcholine, oxytocin (OT), endogenous opioids, cortisol, glutamate, and gamma-

amino butyric acid (GABA) (McDougle *et al.*, 2005; Lam *et al.*, 2006). There is little replicated research that supports the role of norepinephrine and endogenous opioids in autism. Findings on central dopamine turnover are conflicting, so no conclusion is yet possible. OT and arginine vasopressin (AVP) are important regulators of complex social behaviors (Donaldson & Young, 2008; Heinrichs *et al.*, 2009). There have been some reports of differences in levels of peripheral OT and AVP in children with autism compared to age-matched controls (Modahl *et al.*, 1998; Green *et al.*, 2001; Al-Ayadhi, 2005), but peripheral levels do not necessarily reflect central levels (Bartz & Hollander, 2006). Moreover, GABA abnormalities in blood and platelets have been reported in individuals with autism (Rolf *et al.*, 1993). Post mortem studies have identified widespread decreased number of GABA receptor binding sites (Oblak *et al.*, 2009). Fatemi *et al.* (2009) also suggest widespread decreases in expression of GABA synthetic enzymes and GABA receptors in a variety of brain regions.

Observations of immune system abnormalities in ASD have been noted including fetal protein reactive IgG antibodies in plasma from mothers of children with autism, maternal infection, and dysregulated cytokine signaling (Braunschweig *et al.*, 2012). In addition, inflammation in the brain has been reported in post mortem brain specimens of individuals with ASD, suggesting that this is an area worthy of further investigation (Gesundheit *et al.*, 2013).

Neuropathology findings and post mortem studies

Post mortem studies of brain tissue offer the possibility of studying the functional impact of genetic variants in ASD and understanding, at a microscopic level, some of the structural and functional brain imaging findings. Unfortunately, current studies in this area are hampered by poor tissue quality, small sample sizes and confounding factors such as cause of death (Schumann & Nordahl, 2011). Many different neuropathological changes have been described in post mortem samples including macrocephaly, acceleration and deceleration in brain growth, increased neural packing, decreased cell size in the limbic system and decreased Purkinje cell number in the cerebellum. Abnormalities in organization of the cortical minicolumn, representing the fundamental subunit of vertical cortical organization may underlie the pathology of ASD and result in altered thalamocortical organization, cortical disinhibition and dysfunction of the arousal-modulating system of the brain.

Brain imaging

One of the most widely replicated findings in ASD is the increased head size and brain volume (mainly due to increased volumes in frontal lobes and anterior temporal regions) most notably in the preschool period (Bailey *et al.*, 1993; Courchesne

et al., 2007). Neuroimaging methods such as magnetic resonance imaging have identified other abnormalities that appear consistent with some of the proposed social communication and EF deficits identified using psychometric and neuropsychological testing paradigms (Verhoeven *et al.*, 2010; see Chapter 11). A recent meta-analysis of voxel-based global gray matter volumes (using data from 24 independent data sets of adolescent and adult subjects with ASD and healthy controls) has found consistent evidence of reduction in gray matter volumes in the bilateral amygdala-hippocampus complex and the bilateral precuneus and a small increase in gray matter volume in the middle-inferior frontal gyrus (Stanfield *et al.*, 2008). The meta-analysis included studies of adults and adolescents with ASD but only the gray matter volume in the right precuneus was higher in adults than in adolescents with ASD. These findings appear to confirm the crucial involvement of structures linked to social cognition in ASD (Via *et al.*, 2011).

With technological advances, there has been a remarkable increase in studies looking at brain function both during resting states and during specific tasks in individuals with ASD (mostly adults and those who are higher functioning) (see Chapter 11). Studies have focused on brain connectivity between the “social brain” and other regions of the cortex. Systematic reviews and meta-analyses are few but do conclude that there is ineffective integration across brain regions, especially frontal and more posterior cortical regions (Philip *et al.*, 2012). There may be, by contrast, enhanced local connectivity especially in the parietal-occipital regions (Minshew & Keller, 2010) associated with an increased reliance on visual-spatial abilities for visual and verbal reasoning. This work has been extended by more recent work using diffusion tensor imaging to assess white matter integrity. In general, studies show that there are abnormalities in measures of white matter, particularly in those pathways integrating higher order cognitive processes or complex social-emotional processing (Ameis & Szatmari, 2012). A recent meta-analysis has emphasized the role of the superior longitudinal fasciculus, uncinate fasciculus and corpus callosum in understanding the long-distance underconnectivity model of ASD (Aoki *et al.*, 2013).

Assessment

In recent years, a number of evidence-based clinical guidelines and practice parameters have been published in several countries (Le Couteur, 2003; Johnston & Hawken, 2007; Scottish Intercollegiate Guideline Network, 2007; Ministry of Health and Education, 2008; NICE, 2011). Evidence based guidelines, if implemented, are an effective way of disseminating research findings and examples of agreed best practice with the aim to improve and standardize clinical care in community and hospital settings (Davis & Taylor-Vaisey, 1997).

With the increased awareness and recognition that ASDs are relatively common (Centers for Disease Control and Prevention,

2012), there is pressure on local community child health and child and adolescent mental health services to identify and make an appropriate diagnosis as early as possible. The best practice would also recommend the provision of a comprehensive skill- and need-based assessment for the affected individual and their family or carers to inform the development of an individualized education and management plan (see Chapter 32). Timely diagnosis and planning are important for access to effective psychoeducation, interventions, and support (Keenan *et al.*, 2006; see Chapter 32).

Although there are no pathognomonic signs or symptoms of ASD, a number of the national clinical guidelines provide detailed information about the types of signs and symptoms that are commonly observed in preschool, school-aged children and adolescents with a possible ASD (NICE, 2011).

Several authors and guidelines highlight the so-called “Red Flags” for an immediate “fast track” referral of certain “high risk” groups for an ASD specific assessment (Johnson *et al.*, 2007; Allison *et al.*, 2012). For example, a history of loss of speech and early language in a young child under the age of 3 years, is highly suggestive of a possible ASD (Baird *et al.*, 2008; Pickles *et al.*, 2009).

For children with a diagnosis of ASD, review and re-assessment, especially at times of transition (such as starting in education, changing school, onset of adolescence or emerging into early adulthood) are likely to be beneficial either in anticipation of possible change in circumstances or if there is evidence of deterioration, onset of a mental health problem, or a new disorder such as epilepsy. Furthermore, some children and youth may not have been identified or assessed during the early years, but additional developmental, social, and academic pressures or the increased expectations of the school years may lead to symptoms and behaviors that require a multidisciplinary ASD diagnostic assessment at a later stage. All guidelines published in the last decade recommend a multi professional approach for the ASD diagnostic assessment that: responds to the parents’/carers’ and when appropriate, the child or youth’s concerns; makes the best use of existing information about the child or youth and combines assessment information from a variety of sources. Moreover, these processes reveal the differential diagnosis and identification of any co-occurring condition(s) (see Tables 51.1 and 51.2).

The core components of an ASD diagnostic assessment include:

- an ASD specific developmental history using the framework of published internationally agreed diagnostic criteria (ICD-10; DSM-IV-TR; DSM-5; American Psychiatric Association, 2013; World Health Organization, 1992). Most guidelines indicate that using a published standardized diagnostic instrument may assist this process.
- medical history including a prenatal and perinatal history, identification of any relevant past and/or current health conditions and risk factors such as a history of possible epilepsy, and family history to identify genetic disorders, recognized medical and mental health conditions.

Table 51.1 Differential diagnosis.

Consider the following differential diagnosis for autism and whether specific assessments are needed to help interpret the autism history and observations

- Neurodevelopmental disorders:
 - Specific language delay or disorder
 - Intellectual disability or global developmental delay
 - Developmental coordination disorder (DCD).
- Mental and behavioral disorders:
 - Attention deficit hyperactivity disorder (ADHD)
 - Mood disorder
 - Anxiety disorder
 - Attachment disorders
 - Oppositional defiant disorder (ODD)
 - Conduct disorder
 - Obsessive compulsive disorder (OCD)
 - Psychosis.
- Conditions in which there is developmental regression:
 - Rett syndrome
 - Epileptic encephalopathy.
- Other conditions:
 - Severe hearing impairment
 - Severe visual impairment
 - Maltreatment
 - Selective mutism.

National Institute for Health and Care Excellence (2011) CG 128 Autism diagnosis in children and young people: recognition, referral and diagnosis of children and young people on the autism spectrum. Available from <http://guidance.nice.org.uk/CG128>. Reproduced with permission.

Source: Adapted from National Institute for Health and Care Excellence.

- physical examination including an assessment for congenital anomalies, any evidence of skin conditions, evaluation of growth, and measurement of head circumference.
- individual ASD specific assessments (through direct interaction and observation usually in more than one setting). Observational assessment may include the use of an ASD-specific tool such as the Autism Diagnostic Observation Schedule (ADOS) (Lord *et al.*, 2000, 2012b) or the Childhood Autism Rating Scale (CARS) (Schopler *et al.*, 1980, 1986).
- other individual assessments depending on the clinical presentation.
- individual assessments such as vision or hearing, cognitive, sensory, perceptual, motor co-ordination, and psychological investigations to complete a skill- and need-based profile (see Chapters 32–35).

The ASD specific developmental history, ASD observational assessments and standardized individual assessments should all be undertaken by clinicians with experience assessing and working with children and youth with ASD across the ability range. A number of ASD rating scales and diagnostic instruments have been developed that can provide structure and high quality standardized information as part of the referral and diagnostic process but these measures should not be used in the absence of sound clinical knowledge of ASD (Charman & Gotham, 2013).

Table 51.2 Coexisting conditions.

Consider whether the child or young person may have any of the following as a coexisting condition, and if suspected carry out appropriate assessments and referrals:

- Mental and behavior problems and disorders:
 - ADHD
 - Anxiety disorders and phobias
 - Mood disorders
 - Oppositional defiant behavior
 - Tics or Tourette's syndrome
 - OCD
 - Self-injurious behavior.
- Neurodevelopmental problems and disorders:
 - Global delay or intellectual disability
 - Motor coordination problems or DCD
 - Academic learning problems, for example, in literacy or numeracy
 - Speech and language disorder
- Medical or genetic problems and disorders:
 - Epilepsy and epileptic encephalopathy
 - Chromosome disorders
 - Genetic abnormalities, including fragile X
 - Tuberous sclerosis
 - Muscular dystrophy
 - Neurofibromatosis.
- Functional problems and disorders:
 - Feeding problems, including restricted diets
 - Urinary incontinence or enuresis
 - Constipation, altered bowel habit, faecal incontinence, or encopresis
 - Sleep disturbances
 - Vision or hearing impairment.

Source: Adapted from National Institute for Health and Care Excellence.

The four most commonly used diagnostic instruments for ASD include three semi-structured instruments for obtaining a developmental history (Autism Diagnostic Interview-Revised (ADI-R)(Lord *et al.*, 1994; Rutter *et al.*, 2003); Diagnostic Interview for Social and Communication Disorders (DISCO) (Leekam *et al.*, 2002; Wing *et al.*, 2002) and Development, Dimensional and Diagnostic Interview (3di) (Skuse *et al.*, 2004) and one observational measure (the ADOS (Lord *et al.*, 2000, 2012b). For details refer to NICE (2011). Although these and other instruments are widely used in research and clinical practice, they cannot be used in isolation, are usually time consuming and require dedicated training. They provide standardized methods for gathering detailed descriptions of behavior that when integrated with sound clinical expertise in the variable presentation of ASD, will inform an individualized management and educational plan for a child or young person with ASD. Furthermore, there are little published data on the psychometric properties of these measures when used in community clinical settings or other models of health-care service configuration. At present there is no evidence to recommend any one measure for universal clinical practice.

All ASD diagnostic assessments should include a physical examination by a medically qualified practitioner (with expertise in ASD) to assess general development taking into account those factors associated with an increased risk of autism/ASD (NICE, 2011; see Chapter 35). The examiner requires the skills and knowledge to consider the differential diagnosis and identify dysmorphic features, developmental regression (such as Rett syndrome, epileptic encephalopathy), specific genetic conditions such as the fragile X chromosomal anomaly, muscular dystrophy, neurofibromatosis, Tuberose sclerosis; medical conditions such as epilepsy, overgrowth syndromes; neurodevelopment disorders (including Developmental Coordination Disorder (DCD)); and other conditions (including severe sensory and perceptual difficulties, severe hearing impairment, severe visual impairment and child maltreatment) that may also require further investigations. Other problems such as gastrointestinal symptoms and functional impairments of sleep and eating are also common. Any of these conditions and/or problems may have a substantial adverse impact on the child and family. Identification should lead to referral to the relevant specialist professional.

Any further physical and medical investigation such as genetic testing for specific genetic syndromes or mutations, or use of specific tests (such as electroencephalogram (EEG), magnetic resonance imaging (MRI)) should not be performed routinely but based on clinical indications such as family history, dysmorphism or abnormalities in growth (see Chapter 35). In some parts of the world, comparative genomic hybridization arrays are now recommended within professional clinical best practice guidelines to be used as first line investigations (Manning & Hudgins, 2010; Miller *et al.*, 2010) especially in the presence of intellectual disability or dysmorphism.

Assessment of family strengths and needs and the social and cultural context for the child or young person is important as part of a skill- and need-based assessment (see Chapter 32). Evidence is emerging that the burden of raising a child with ASD is greater in families with a child with ASD compared to children with other mental health and developmental disorders (Dumas *et al.*, 1991; Sivberg, 2002; Abbeduto *et al.*, 2004). A range of factors including severity of ASD and problem behaviors, social support, religion, the family's attitude to the diagnosis (reframing) and psychological acceptance are likely to influence family adaptation to ASD and impact on parent mental health (Taunt & Hastings, 2002; Weiss *et al.*, 2012).

The conclusions of an ASD multidisciplinary assessment should be collated as a profile of the child or young person. The findings should include a best-estimate clinical diagnosis, the identification of any co-occurring conditions and a summary of skills and needs for the child or young person and their family (see Chapter 32).

Treatments

An individualized management plan for the child/youth with ASD and their family or carers needs to be developed. Over time,

intervention plans will change in response to the child's developmental profile, their circumstances and the onset of any additional physical and mental health disorders. Management and support are likely to include a number of different agencies and professionals working collaboratively (NICE, 2013).

The goals of interventions include:

- Reduce the core symptoms and behaviors of ASD.
- Enable an individual to achieve their own potential.
- Treat any co-occurring problems or symptoms that impair developmental progress or cause significant distress for the affected individual and other family members or carers.
- Support the family and those providing the care and interventions for the affected individual through education and specific evidence-based strategies.

There are many different interventions and treatments proposed for ASD and the additional problems that individuals with ASD experience. It is unfortunate that most interventions have not been independently and adequately evaluated. To date, there are few systematic reviews and meta-analyses to inform an evidence-based approach for the management of affected children at different ages. National and professional organizations have published practice guidelines which provide general and specific recommendations usually based on the best clinical practice (Myers *et al.*, 2007; Scottish Intercollegiate Guidelines Network, 2007; Ministry of Health and Education, 2008; AHRQ, 2011; Warren *et al.*, 2011a; NICE, 2013).

Psychosocial and behavioral interventions for the management of core features of ASD

Despite the limited evidence base, there is a growing consensus that early identification and access to specific psychosocial interventions delivered by trained professionals is likely to improve the outcomes for some children with ASD (NICE, 2013). Using recent systematic reviews and meta-analyses published since 2005, Magiati *et al.* (2012) and Reichow *et al.* (2012) have identified that early intensive behavioral intervention (EIBI) is the most frequently evaluated intervention in preschool children with ASD. These interventions are largely based on the model of Applied Behavioral Analysis (ABA) principles and other comprehensive behaviorally and developmentally based programmes for young children with ASD such as those developed by Lovaas (1987; McEachin *et al.*, 1993). The evaluation of EIBI and other interventions include "efficacy" trials undertaken in university or specialist clinics under laboratory conditions and some effectiveness studies conducted with parents in community, "real-life," settings. Most studies compare the intervention with treatment as usual or no treatment and do report a positive outcome particularly in communication skills. An increasing number of studies have reported on early interventions such as the Early Start Denver Model (ESDM), Learning Experiences and Alternative Programme for Preschoolers and their Parents (LEAP), Preschool Autism Social-Communication Trial (PACT) and Treatment and Education for Autistic and Related Communication Handicapped Children (TEACCH) (Rogers & Vismara, 2008; Eikeseth, 2009; Dawson *et al.*, 2010;

Green *et al.*, 2010; Virués-Ortega, 2010; Strain & Bovey, 2011; Warren *et al.*, 2011a, b). In contrast to the Lovaas type models, these psychosocial interventions are developmentally oriented, may include principles of ABA and often focus on social communication. For preschool children, the interventions usually involve teaching parents, carers, or teachers strategies to increase joint attention skills and reciprocal communication often through interactive play and action routines (Kasari *et al.*, 2006; Yoder & Stone, 2006; Green *et al.*, 2010; Kaale *et al.*, 2012). The improvements in outcome are usually either in proximal measures specific to the intervention such as joint attention or more general measures of intellectual, language and/or adaptive function. Very few studies assess impact on autism behaviors and no studies to date have investigated longer-term outcomes (Green *et al.*, 2010).

For older school-aged children and young people, a small number of systematic reviews have identified a limited number of studies evaluating interventions, such as social skills training for improving social communication and peer-mediated social communication interventions (Maglione *et al.*, 2012; Reichow *et al.*, 2012). As with preschool children, interventions have been delivered in a variety of contexts including home, clinic settings, and educational/school-based provision. The studies to date are of relatively poor quality and although there is some evidence that greater intensity and longer treatment duration may lead to improved outcome, further research with manualized interventions and appropriate well-validated outcome measures is needed.

The recently published NICE Clinical Guideline (CG) 170 (2013) clinical guidelines development group judged that the social-communication programmes may help address social isolation. There is, however, little evidence for interventions aimed at the core ASD feature of restricted, repetitive behaviors, or sensory sensitivities, either as a direct or indirect outcome. Some psychosocial interventions evaluation studies have included repetitive behaviors and reported either no change or a small treatment effect from parent training and/or antipsychotic medication (Dawson *et al.*, 2010; Green *et al.*, 2010; Scahill *et al.*, 2012). There is evidence (Maglione *et al.*, 2012) that augmentative forms of communication such as the Picture Exchange Communication System (PECS) can improve the communication skills of young children with ASD and should be part of the comprehensive treatment plan, but may not be as effective as originally thought.

Other Interventions for the treatment of core features of ASD

Interventions such as sensory integration therapy (SIT) and auditory integration training (AIT) have been proposed to alleviate hyper- or hypo-sensitivity to certain stimuli (Kadar *et al.*, 2012) and to particular frequencies and sounds (Bettison, 1996). However, systematic reviews indicate that the study designs are of poor quality and the evidence is inadequate to recommend SIT as an evidence-based treatment for ASD (Baranek, 2002; Case-Smith & Arbesman, 2008). For AIT,

systematic reviews (Baranek, 2002; Case-Smith & Arbesman, 2008; Parr, 2008; Sinha *et al.*, 2011) have indicated that the evidence is insufficient to conclude that these are effective treatments for individuals with ASD. Moreover, the reviews highlighted concerns about hearing loss as a result of listening to various sounds of high volume.

Visual therapies, music therapy and use of restricted diets and dietary supplementation such as omega-3 fatty acids, have also been used by families to treat both core ASD symptoms and associated problems such as ADHD-like behaviors, gastrointestinal problems, and sensory disturbances (Baranek, 2002; Gold *et al.*, 2006; Hodgetts & Hodgetts, 2007; Case-Smith & Arbesman, 2008; Parr, 2008; Millward *et al.*, 2009; Buie *et al.*, 2010; James *et al.*, 2011; Sinha *et al.*, 2011). The gluten free, casein free diet (GFCFD) is the most frequently implemented restrictive dietary intervention for individuals with ASD. Three reviews have been published highlighting the poor quality of the studies and the lack of evidence for this intervention (Parr, 2008; Millward *et al.*, 2009; James *et al.*, 2011). With respect to fatty acid supplementation, James *et al.* (2011) concluded that there was no evidence of a difference between individuals with autism who received omega-3 fatty acids and a placebo group. With regard to older adolescents and young adults, a recent systematic review of vocational interventions has reported that despite the small number of studies and the poor quality, there is some evidence that vocational programmes may increase employment success for some individuals with ASD (Dove *et al.*, 2012).

Systematic reviews have also demonstrated some evidence that the use of antipsychotic medications (such as risperidone) can reduce repetitive behaviors in children and adolescents (usually in association with irritability and other behaviors that challenge) though there is some disagreement in the field (RUPP, 2005; Jesner *et al.*, 2007; McPheeters *et al.*, 2011). For example, taking into account the evidence for statistically significant adverse effects associated with antipsychotics (see NICE CG 170, 2013 for an updated review) the NICE clinical guideline development group did not recommend antipsychotic medications for the treatment of core symptoms of ASD. A systematic review by Williams *et al.* (2010) has examined the effectiveness of selective serotonin reuptake inhibitors (SSRIs) in treating symptoms associated with ASD and found that there are no data supporting the use of SSRIs in improving symptoms of individuals with ASD and strong data recording the incidence of adverse effects (see Chapter 43). Finally, there is now sufficient evidence to recommend that certain interventions should not be used to treat core features of ASD. These include long-term chelation therapy, hyperbaric oxygen, and secretin (NICE, 2013).

Management of associated and co-occurring conditions

All published clinical guidelines identify the importance of the early identification and implementation of evidence-based treatment for any recognized medical problems. For the

management of commonly occurring conditions such as sleep problems as with other difficulties, a combination of a detailed specific assessment leading to a behavioral management plan to improve sleep hygiene should be implemented before considering the use of medication (NICE, 2013). Systematic reviews by Guenole *et al.* (2011) and Rossignol and Frye (2011) examined the effects of melatonin in improving sleep disturbances and found that melatonin shortened time to falling asleep but did not necessarily prolong sleep duration (see Chapter 70).

Identification and treatment of co-occurring behavioral and mental health problems

It is now widely recognized that children and young people with ASD have higher rates of co-occurring mental health disorders than individuals in the general population and children with other disabilities (Leyfer *et al.*, 2006; de Bruin *et al.*, 2007; Simonoff *et al.*, 2008, 2012; Joshi *et al.*, 2010; Van Steensel *et al.*, 2011). These include ADHD; other behavioral and mental health problems including Oppositional Defiant Disorder, anxiety, mood disturbance, Obsessive Compulsive Disorder; behaviors that challenge as well as catatonia, a rare but debilitating comorbidity (Wing & Shah, 2000). Most clinical guidelines recommend implementation of evidence-based interventions for the co-occurring disorder but indicate that modifications in the delivery of the intervention may be required to meet the needs of the person with ASD.

For example, children and young people with ASD with good verbal and cognitive skills and comorbid anxiety disorder may have the capacity to engage in a course of cognitive behavior therapy (CBT). There is evidence that a group or individual-based intervention adjusted to the needs of children with ASD can be effective (see Chapters 38 and 60; Sofronoff *et al.*, 2007; Drahota *et al.*, 2011; NICE, 2013). Similarly for the treatment of co-occurring ADHD, a combination of family and school-based behavioral interventions could be instigated and later, if required, supported by a trial of medication. However, the use of stimulants and other recommended second line medications for the treatment of ADHD-like symptoms show that the response rate is lower than for children and adolescents without ASD and with a higher rate of adverse side effects (see Chapter 55; NICE, 2013). SSRI's have also been used to treat OCD, some severe anxiety disorders and mood disorders in ASD but with no real evidence of efficacy (McPheeters *et al.*, 2011; see Chapters 43, 60, 61 and 63).

To anticipate and prevent behaviors that challenge, identifying factors that increase risk such as sensory sensitivities, changing circumstances, physical or mental illness, exploitation, bullying at school, or abuse should always be considered and the necessary actions put in place. A functional behavioral analysis based on a thorough understanding of precipitating circumstances and reinforcing factors needs to be undertaken by staff with an understanding of ASD before medication is initiated (see Chapter 38).

Antipsychotic medication has been used to ameliorate associated symptoms such as aggression and irritability. The evidence appears to be consistent in demonstrating a positive impact on these symptoms (McPheeters *et al.*, 2011; Dove *et al.*, 2012). The starting dose should be low, aiming for the minimum effective dose and carefully monitoring for adverse effects with a plan for regular review and eventual discontinuation (see Chapter 43).

Educational issues

In most countries over recent decades, the emphasis has been on inclusive environments for the education of children with special education needs including ASD (see Chapters 41 and 42). However, education for children with ASD includes both the acquisition of culturally valued skills in settings that promote full participation and the need to learn specific skills and social understanding to “compensate” for their ASD. There is no evidence of the effectiveness of different educational settings, nor how children with ASD experience education in the context of “real-world” classrooms. Furthermore, although some studies have attempted to evaluate interventions for young children, the educational needs of older children and those in post compulsory education, consideration of diversity of need and, most importantly, the views of young people about their experiences of education have all been relatively neglected. The efficacy of one comprehensive programme (TEACCH) that has been incorporated into a wide range of education settings has been reported in one meta-analysis. Moderate to large gains in social behavior and behaviors that challenge has been reported, but much smaller effect sizes exist on more cognitively related outcomes (Virues-Ortega *et al.*, 2013). Social skill interventions and emotional learning programmes are often carried out in schools and there is some evidence of efficacy for these interventions (Reichow & Volkmar, 2010).

Family support

Some studies have shown that family stress can be modified (see Chapter 39) (Dunn *et al.*, 2001; Hastings & Brown, 2002; Benson & Karlof, 2009). The recently published NICE CG170, 2013 report a meta-analysis of three psychosocial intervention studies, which were of small sample sizes with relatively poor methodologies. For this reason, the guideline development group concluded that as there was to date insufficient evidence to recommend interventions for improving parental stress, mental health, or quality of life, the focus of intervention should be the management of behaviors that challenge. The benefits of involving parents as the so-called ‘co-therapists’ has long been recognized particularly with respect to the maintenance of treatment effects and generalization of learned responses across settings (Schopler *et al.*, 1982; Howlin & Rutter, 1987). However, for parents such therapeutic tasks may also be a source of increased stress. The range of ways to engage with parents includes individual work in the home or clinic, group-based

interventions and/or parents taking on the role of parent peers/mentors to help other parents learn new skills.

Transition planning

There is an increasing recognition of the difficulties individuals with ASD have with anticipating and managing change from minor apparently irrelevant changes to larger changes such as moving into a new nursery group or classroom, moving to a larger secondary school, leaving school and going to college or looking for paid employment. As individuals approach early adulthood there is an expectation that they should take on more responsibility for self-management of their own condition. While this is a key issue, there is little literature based on clinical trials evaluating the effectiveness of transition planning interventions (Watson *et al.*, 2011).

Future developments and necessary research

There has been a remarkable increase in the knowledge base for ASD since the first edition of this textbook. Although progress has been made in measurement and diagnostic tools, in understanding prevalence and etiology and in developing evidence-based treatments both for core symptoms and comorbid conditions, much remains to be learned. Throughout the history of ASD research, there has been a tension between understanding autism as a unitary diagnosis at the same time acknowledging the complexity implied by considering autism as a spectrum disorder. Multiple unitary explanations of phenomenology, etiology, and underlying cognitive impairments have encouraged different schools to promote treatments based on separate paradigms of understanding. But the reality is one of complexity and heterogeneity at multiple levels creating major challenges for researchers, families, clinicians, and policy makers alike.

In terms of basic research, new paradigms are needed to uncover not only heterogeneous genetic mechanisms but also the functional impact of those genetic variants, including animal models and imaging studies. Cognitive behavior neuroscience and molecular genetic findings together might identify gene–environment interactions in particular individuals with ASD. Appreciation of this heterogeneity of ASD also has important clinical implications. Personalizing care by identifying effective treatment for each individual at appropriate points in development should be a key priority, working in partnership with young people with ASD and their families/carers. Further research is needed into how individuals with ASD access health and social care services. A key issue will be to identify early risk markers for ASD and co-occurring conditions that are amenable to interventions that could reduce the likelihood of a cascade of further difficulties with the inevitable adverse impacts on later lifetime functioning. Finally, it is not known how best to disseminate training, knowledge, and the best practice about

particular interventions among all professionals in contact with individuals with ASD. Overall the ultimate goal is for a sufficiently accurate evidence base to inform effective intervention planning for every individual with ASD and their family. This evidence base includes an individualized genetic profile, in combination with the identification of relevant environmental and family factors.

Acknowledgments

We would like to thank Sofia Al Balkhi, Laura Fox (Canada) together with Hannah Merrick (Newcastle University), Dr. Hasan Aman (Northumberland. Tyne & Wear NHS Foundation Trust) (UK) for their assistance with the literature searches and Rachael Taylor (UK) for her dedicated administrative support, leading to the completion of this chapter.

We also appreciate the assistance provided by the NICE for their permission to include Tables 51.1 and 51.2 from the NICE CG 128, 2011 and Sarah Carrington & Rachel Kent, Cardiff University for permission to reprint Figure 51.1.

CHAPTER 52

Disorders of speech, language, and communication

Courtenay Frazier Norbury¹ and Rhea Paul²

¹Department of Psychology, Royal Holloway, University of London, Surrey, UK

²Department of Speech-Language Pathology, College of Health Professions, Sacred Heart University, Fairfield, CT, USA

Introduction

Distinguishing speech, language, and communication

Communication is the transmission of information (a message) between a source and a receiver, using a common signaling system and is an essential function of many social animals, including humans. Honey bees, for example, perform a “dance” when they return to the hive, using movement patterns to indicate the direction and distance of food. Human communication includes body language, gesture, and facial expression to convey messages. Humans have also evolved a unique form of communication that appears to be unshared by other species, *language*. Language is a complex, formal system that makes use of a finite number of units (sounds and words) that can be combined in rule-governed ways to convey an infinite number of meanings. Language, too, can take a variety of forms; it can be written or expressed with manual signs, for example. However, the most widely used form for expressing language is through *speech*. Speech is composed of a relatively small set of sounds, or phonemes, produced by means of articulation of the oral structures (lips, tongue, teeth, and palate), which are used to modify the vibration of air, initiated by the vocal cords, as it passes through the oral cavity, resulting in acoustic patterns we perceive as speech. The sounds of speech are ordered sequentially according to language-specific rules in order to produce words recognized by users of a particular language. The relationship among communication, language, and speech is represented in Figure 52.1. *Communication* is the broadest term, encompassing a wide range of methods of conveying information; *language* is a specific type of communication governed by rules that allow novel combination of elements; *speech* is a particular way of expressing language, through orally produced units of sounds, combined, again, in rule-governed ways.

Disorders of communication can occur at any level within this system, and some communication disorders can affect one level without affecting others. Consider Dana:

Dana is a bright, garrulous 7 year old, who sounds like a much younger child when she talks. She makes lots of errors in her speech, including substituting one sound for another (saying “wabbit” for “rabbit”) leaving off sounds (saying “cool” for “school”) and syllables (“Saying “mato” for “tomato”), and reversing sounds (saying “pesgetti” for “spaghetti”). The result of these errors is that she is often hard to understand, even though she has lots to say, uses long sentences and understands what others say to her. When people don’t understand her, she tries repeating, using gestures and facial expression to repair the communication. She seems very eager to talk and engage with others, despite her occasional frustration at being misunderstood.

Dana is a child with a speech disorder. Her communication (desire to exchange information) and her language (ability to use words and sentences) appear to be developing typically. But Nick is another story:

Nick is a nine-year old boy who can produce sounds clearly, but his language is impaired. He produces short, immature sentences that leave off word endings (“I have two shoe; Mommy help me at the store), uses incorrect forms of words (Me like ice cream; He goed home), and has trouble finding the words he wants to say (“For lunch I had, you know, that spiky thing, yellow inside). Nick likes to play with other children and enjoys talking, but has limited means at his disposal for expressing and elaborating his intentions.

Nick’s speech is intact and he, too, is motivated to communicate, but his language disorder disrupts successful communication; he has not acquired the words and the grammatical rules that would allow him to express the ideas he has in an age-appropriate way. His communication style is in sharp contrast to Ben’s:

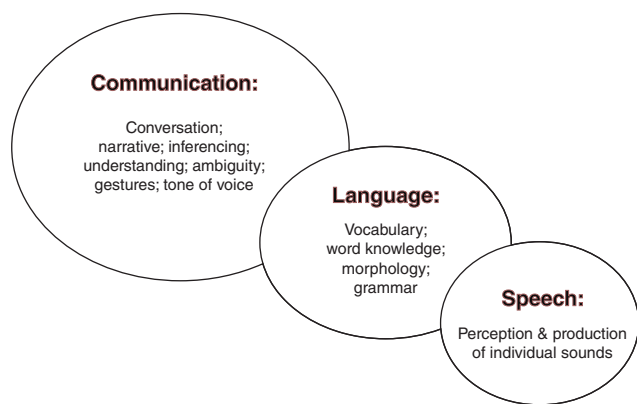

Figure 52.1 Speech, language, and communication and their component skills.

Ben is an extremely bright five-year-old. He uses precise articulation and long, complex sentences to express himself, but he isn't always successful at talking with others. He likes to play with action figures, and narrates long scenes and dialogue from his favorite films and video games. He is reluctant to interact with other children because he is often confused about what they are saying. If they tell a joke he thinks they are laughing at him, because he often doesn't get the punch line. He prefers to interact with adults, but sometimes gets in trouble for not responding the way they want him too. For example, mum might ask, 'can you shut the door' and then gets cross when he replies 'yes' but doesn't actually move to shut the door. He often interrupts adults to talk to them but they can't really follow what he's trying to say because he leaves out important details.

Ben does not have much difficulty with the form of his speech or language. Rather, his ability to use language skills to communicate effectively with other people, or *pragmatics*, is affected. Children who have difficulties with pragmatics and using language for social exchanges may be diagnosed with “social communication disorder.” Dana, Nick, and Ben exemplify children with communication disorders that affect one level of communication more or less discretely. Many children with communication disorders, though, have impairments that affect several of these levels and are continuous with a range of neurodevelopmental disorders including specific learning disorders (see Chapter 53), attention deficit hyperactivity disorder (ADHD) (see Chapter 55) and autism spectrum disorder (ASD, see Chapter 51).

In this chapter, we discuss the three major categories of communication disorder—speech, language, and social (pragmatic) communication disorder (SPCD), as defined by the diagnostic and statistical manual of mental disorder (DSM)-V (American Psychiatric Association, 2013). We begin by considering assessment of children with suspected communication disorder. We then outline typologies for the three categories of communication disorder, addressing issues of differential diagnosis within communication disorders and between these and other neurodevelopmental disorders (see also Chapter 3). We focus most on language disorders, as these have the greatest

evidence base and likely impact on mental health, given the limited research base for SPCD that exists currently. Finally, we provide an overview of current intervention approaches for each category of communication disorder.

General principles of assessment

The evaluation of children suspected of communication disorder is generally undertaken by speech-language pathologists or therapists (SLTs), specialists trained in the anatomy, physiology, psychology, linguistics, and pedagogy of communication and its disorders. The general process of assessment often follows the progression depicted in Figure 52.2. The process may begin with a referral from a clinician, such as a health visitor, general practitioner, or child psychiatrist, or with a screening test administered in an educational setting. Although parents may also self-refer, many parents may not suspect a communication disorder at first and may be more focused on a child's problems with behavior regulation, social interaction, or learning in school. While these difficulties can exist without an underlying communication disorder, it is often the case that a problem in speech or language is masked by more obvious trouble in other areas (Cohen *et al.*, 1998)

For any child referred, it is essential to request a thorough hearing assessment by an audiologist as part of the evaluation, in order to rule out hearing impairment as a potential cause of communication disorder. A case history, including questions about the child's feeding, speech, and hearing history will be used to determine whether early problems in sucking, chewing, and swallowing were present, suggesting potential neuromotor involvement. The case history will also address the child's motivation to communicate and interact with others, as well as use of any compensatory strategies, such as gestures or vocalizations. The forms of speech currently available, whether sounds, words, phrases, or sentences will help determine the level at which to begin the formal assessment and the degree to which the child's speech can be understood by familiar and less familiar people, will also be informative. The interviewer will also want to know if the child is able to follow verbal instructions and respond to others, and what language(s) the child is exposed to at home. With regard to older children, the ability to understand a story or joke will also be of interest.

A second tool frequently used by SLTs is an informal conversational sample, in which the child and clinician engage in talk around objects and/or topics of interest to the child and the clinician observes the child's motivation to communicate and the forms and functions the child's communication takes. This observation allows the clinician to estimate the richness of the child's vocabulary, grammatical complexity, ability to retrieve words, and reply to questions. The observation will also reveal important information about the intelligibility and fluency of speech as well as about the volume, quality, and resonance of the voice. If the child is learning more than one language, the

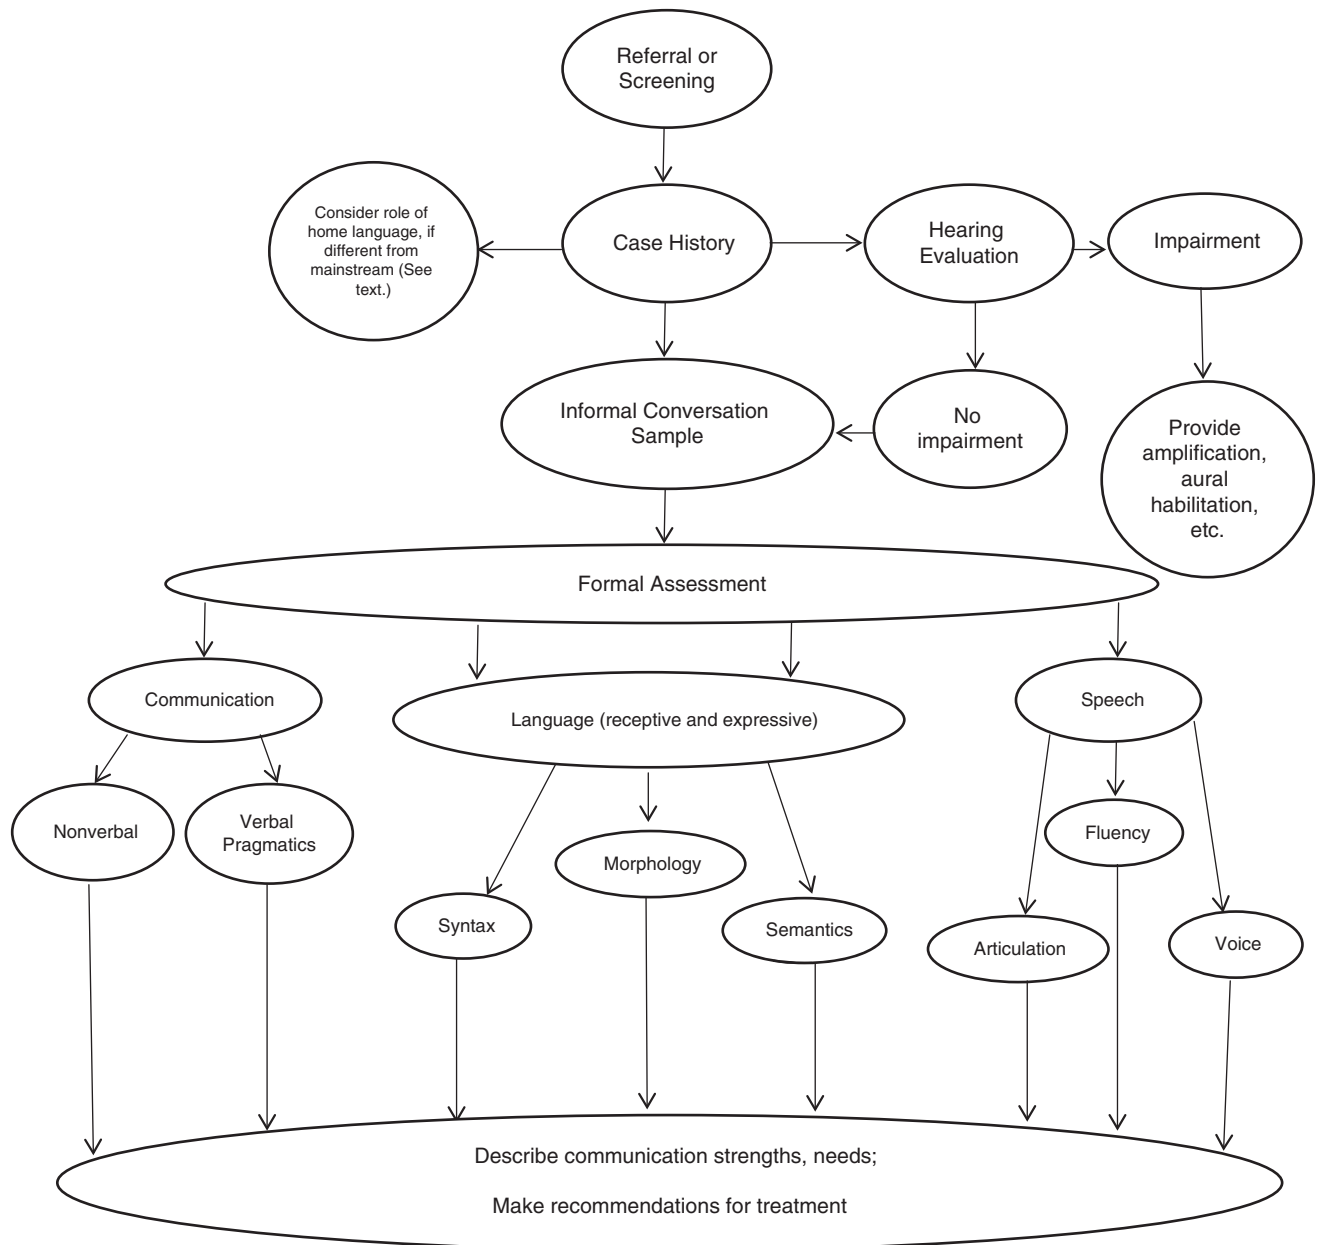

Figure 52.2 Assessment of communication.

clinician may ask parents to interact with the child first in one language and then in the other(s), to observe the child's comfort and fluency in each. Finally, other aspects of development can also be observed, such as the child's play skills, attention capacity, interest in others, motivation to communicate, persistence and frustration tolerance, and so on. These observations can help the clinician determine the forms of interaction that might be most fruitful for a particular child.

The informal speech sample allows the clinician to form a hypothesis about areas of communication strength and weakness. This hypothesis will be tested with the use of formal assessments, such as standardized tests and structured parent

questionnaires and interviews, such as those listed in Table 52.1. Each area of hypothesized weakness will be assessed, as schematized in Figure 52.2. These findings will not only provide a working diagnosis, but should also inform the intervention plan (see **Intervention** section in this chapter, and Chapter 41).

Differential diagnosis of speech disorders

Speech sound disorders affect the intelligibility and quality of the oral language produced. DSM-5 (American Psychiatric Association, 2013) *speech sound disorder* and *childhood onset*

Table 52.1 A sample of formal language assessments in common use.

Area	Assessment tool	Age range	Description
Speech: Articulation	<i>Goldman-Fristoe Test of Articulation—Second Edition</i> GFTA-2; (Goldman & Fristoe, 2000)	2–21 yr	Can be used with Khan-Lewis Phonological Analysis Yields percentile rank by age score Administration time: 10–15 min for single-word portion
	<i>Photo Articulation Test—Third Edition</i> PAT-3; (Pendergrast et al., 1997)	3–12 yr	Provides means and standard deviations for age
Speech: Fluency	<i>Test of Childhood Stuttering</i> (Gillam et al., 2009)	4–12 yr	Uses rapid picture naming, modeled sentences, narration and structured conversation to identify stuttering, judge severity, and monitor progress
Speech: Voice	<i>Voice Assessment Protocol for Children and Adults</i> VAP; (Pindzola, 1987)	3–Adult	Systematic evaluation of vocal pitch, loudness, quality, breath features, and speech rate/rhythm
Language: Semantics	<i>British Picture Vocabulary Scales—Fourth Edition</i> BPVS-3; (Dunn et al., 2009)	2;6 yr–adult	Receptive vocabulary
	<i>MacArthur Bates Communicative Development Inventory</i> (Fenson et al., 1993)	8–36 mo.	Parent checklist of words understood and said, as well as communicative gestures and early word combinations
Language: Syntax	<i>Rice-Wexler Test of Early Grammatical Impairment</i> (TEGI; Rice & Wexler, 2001)	3;0–8;0	Grammatical morphology
	<i>Test for Reception of Grammar-2</i> (TROG; (D. V. M. Bishop, 2003b)	4–adult	Child matches spoken sentence to one of four pictures to assess understanding of grammatical forms
Communication: Narrative	<i>The Bus Story Test</i> (Renfrew, 1991)	3–8	Provides age-equivalent scores for story information value and sentence length
	<i>Test of Narrative Language</i> (Gillam & Pearson, 2004)	5–11	Elicits stories using picture sequences, single pictures and no pictures to measure the ability to answer literal and inferential comprehension questions and narrative discourse
Communication: Pragmatics	<i>Test of Pragmatic Language—Second Edition</i> TOPL-2; (Phelps-Terasaki & Phelps-Gunn, 2006)	6–18 yr	Comprehensive assessment of student's abilities to use pragmatic language effectively
	<i>Children's Communication Checklist-2</i> (Bishop, 2003a, b)	4–16 yr	Parent report of language and pragmatic behaviors with normative scores
Omnibus	<i>Clinical Evaluation of Language Fundamentals—Fourth Edition</i> CELF-4UK; (Semel et al., 2006)	3–6 yr	Concepts, syntax, semantics, morphology
	<i>Preschool Language Scale—Fourth Edition</i> UK PLS-4; (Zimmerman et al., 2009)	Birth–7;11 yr	Language precursors; expressive and receptive semantics, syntax, morphology, integrative thinking, auditory comprehension
	<i>Test for Auditory Comprehension of Language—Third Edition</i> TACL-3; (Carrow-Woodfolk, 1998)	3–9;11 yr	Receptive aspects of: word classes and relations, grammatical morphemes, elaborated sentence constructions
	<i>Test of Language Development—Fourth Edition: Primary</i> TOLD-4:P; (Hammill & Newcomer, 2008)	4–8;11 yr	Receptive and expressive semantics and syntax
	<i>Woodcock Language Proficiency Battery—Revised</i> (Woodcock, 1991)	2–adult yr	Oral language, vocabulary, antonyms and synonyms, reading and writing

Source: Adapted from various sources

fluency disorder. We will briefly describe the clinical presentation of each and discuss differential diagnosis. Intervention procedures typically applied to this class of disorders are outlined in the Intervention section of this chapter.

Speech sound disorder

All human languages make use of a small set of speech sounds, called *phonemes*, to encode meaning. For example, British English uses only 24 consonants and 20 vowels in combination to produce the tens of thousands of words. Children make mistakes when they first start to talk, often leaving out some of the sounds required in adult words (Saying “pay” for *play*, for example), substituting known sounds for some of the more difficult sounds in language (saying “wabbit” for *rabbit*), or distorting some sounds, for example, lisping. In typical development, most of these errors resolve by 4–5 years of age, but for some children they persist for longer than normal. For most children, these persistent errors make them sound immature when they talk, although they can make themselves understood. For others, speech may be mostly unintelligible to people outside the family.

For most children with speech sound disorder, no physical cause is obvious. Instead, the disorder is thought to have its roots in the child’s difficulty in learning to “sort out” the sounds of the ambient language into their appropriate categories. As these categories differ from language to language, it should not be surprising that some children find this difficult. For example, compare this problem to the one Japanese speakers have when they try to distinguish the words, *rice* and *lice*. While the beginning consonants in these words are clearly different to English speakers, Japanese speakers do not have separate categories for the sounds [r] and [l]; only one approximant sound is used in their language. As a result, Japanese speakers have a great deal of difficulty either hearing or producing the distinction between the two words.

Prevalence, prognosis, causes, and correlates of speech disorders

Shriberg *et al.* (1999) estimated the prevalence of speech sound disorders in 6-year-old children at 3.8%. Rates for younger children are much higher, with some studies reporting rates of 15.6% in 3-year-old children (Shriberg *et al.*, 1999; Campbell *et al.*, 2003a, b), but the rate decreases with age, to an overall rate of 1% at school age (McKinnon *et al.*, 2007). Speech sound disorder of unknown origin accounts for the vast majority of these cases. Although the origin of speech sound disorder is unknown, it has been found to run in families, (Newbury & Monaco, 2010) and high rates of comorbidity with both language and literacy disorders are observed, particularly in children whose delays persist to school age (Pennington & Bishop, 2009).

Children with speech sound disorder who receive intervention in the preschool or primary grades generally have a good prognosis for speech normalization. Shirberg *et al.* (1994)

reported that normalization is achieved by most preschoolers even with moderate to severe speech sound delays by 8 years of age, although children with the more severe delays are likely to retain speech sound distortions beyond this age.

Assessment of speech sound disorders

Gordon-Brannan and Weiss (2007) reported levels of intelligibility for children that serve as a benchmark for the assessment of speech. At age 2, 50% of what a child says should be understood by people outside the family; at 3, 75% should be intelligible, and at 4, 100% should be understood, though some errors may still occur that do not impact intelligibility to a great extent. Children who fail to meet these basic intelligibility benchmarks should be referred for assessment. By 8 years of age, all errors should have resolved and children aged 8 and over who have any speech errors, even on only one or two sounds, should be evaluated. Although these residual errors may not impact intelligibility, they do call attention to speech and may result in teasing or other social consequences that can impact development.

Assessment of speech generally consists of both standardized testing (Table 52.1) and analysis of spontaneous speech. An SLT will generally administer a test to determine the child’s speech sound accuracy and the types of speech errors made, whether substitutions, omissions, or distortions of sounds. A sample of spontaneous speech is used to determine the level of intelligibility, by computing the number of intelligible versus unintelligible words. It will also provide a phonetic inventory or a list of all sounds produced, in order to identify any missing sounds that need to be taught. Finally, clinicians use speech samples to identify patterns of error that go beyond a single sound. For example, children often leave off final sounds in words, regardless of what the sound is, or they reduce clusters of consonants to a single consonant, again without regard to the particular consonants in the cluster (e.g., *star* → *tar*). These assessments determine whether intervention is warranted and help to specify the targets of intervention. Assessment for motor speech disorders is similar, although the focus will be on intelligibility rather than on identification of specific speech sound errors.

Childhood onset fluency disorder

Disorders of fluency are characterized by interruptions in the flow of speech with atypical rate, rhythm, and repetitions in sounds, syllables, words, and phrases. This may be accompanied by excessive tension, struggle behavior, and secondary mannerisms, such as eye blinking or arm movements, which give the impression of struggle.

Prevalence, prognosis, causes, and correlates

Dysfluency is quite common in preschool children and is associated with early difficulties in language formulation (Bloodstein, 2006). Seventy-five percent of dysfluent preschoolers recover without intervention (Yairi & Ambrose, 1999), although prognosis for full recovery after age 7 is more guarded. The prevalence of dysfluency in the general school-aged population

is between 0.3% and 1% (McKinnon *et al.*, 2007). The behaviors indicative of persistent dysfluency in preschoolers (Campbell *et al.*, 2003a, b) are:

- Frequent part-word repetitions
- Physical tension and struggle
- Signs of frustration
- Delays in other aspects of speech and language development

The disorder is more prevalent, and more likely to be persistent, in males (Prasse & Kikano, 2008). Over 60% of people who stutter present with concurrent speech and language disorders, the most common of which is speech sound disorder (SSD) (Newbury & Monaco, 2010). Although there are emotional and psychological components to dysfluency, risk for the disorder is also genetically influenced (Kraft & Yairi, 2012).

Assessment and Intervention

Assessment of dysfluency typically has two goals: to describe the dysfluency itself and to assess the impact of the dysfluency on communication and daily living. Description will usually involve analyzing a sample of spontaneous speech and calculating the types and frequency of disruptions. Assessment of the impact of the disorder is usually accomplished through interviews with the client or caregiver. Baseline data from both of these assessments are used to monitor progress throughout the course of intervention.

Intervention for dysfluency generally falls into one of four classes (Ramig & Pollard, 2010):

- *Fluency Shaping.* This method teaches strategies for reducing the occurrence of stuttered speech, which include building from single word to longer utterances while maintaining fluency, management of the breath stream, and reducing the rate of speech.
- *Stuttering Modification.* Rather than attempting to eliminate stuttering, this method aims to modify stuttering so it is less conspicuous and to desensitize the client to the stress of dysfluency.
- *Use of Electronic Devices.* It has long been known that delayed auditory feedback reduces stuttering, leading to the development of compact devices that resemble hearing aids and deliver delayed auditory feedback. These devices have been reported to show some efficacy for some people who stutter (Pollard *et al.*, 2009), but the effect is only present while the device is worn.
- *Parent-implemented.* For young children, parents are often taught techniques to help the child reduce dysfluency.

Voice disorders

Voice disorders are not described in DSM-5, but can be associated with various developmental conditions. Voice disorders are characterized by the abnormal production and/or absences of vocal quality, pitch, loudness, resonance, and/or duration, which is inappropriate for an individual's age and/or sex. In some cases, voice disorders severely limit communication, when, for example, the speaker is unable to generate adequate

volume to make himself heard or when abnormal growths on the vocal folds interfere with the vibration that underlies speech. In other cases, though, voice disorders do not preclude communication; instead they distract the listener and call attention to the form of the communication rather than its message. In children, voice disorders generally fall into two broad classes: vocal strain and resonance disorders.

Shouting, the use of unnatural pitch (to sound older or more masculine), perpetual loud talking (to be heard above siblings or classmates), or singing (in choir) can lead to vocal strain, as can excessive throat clearing associated with compulsive disorders such as Tourette's syndrome. Vocal strain can lead to the development of vocal nodules, polyps, or contact ulcers, which may require surgical intervention. Many resonance disorders are caused by malformations of the speech mechanism. Children with cleft palate, who may lack the tissue and musculature to separate the oral and nasal cavities, allowing air to leak into the nose during speech, often show hypernasal resonance. Muscular weakness, such as that observed in cerebral palsy, can also affect these functions. In addition, many children with ASDs exhibit hypernasal speech, without any structural or known neuromuscular abnormalities.

Prevalence, prognosis, causes, and correlates

McKinnon *et al.* (2007) estimate the prevalence of voice disorders in children to be 0.12%, although estimates among preschool children are as high as 3.9% (Duff *et al.*, 2004). Vocal strain is observed in children without comorbid disabilities. Resonance disorders, on the other hand, usually accompany a variety of conditions including cerebral palsy, Down syndrome, cleft palate, ASDs and, less frequently, language disorders.

Assessment and Intervention

In the case of resonance disorders, the amount of airflow from the nose during speech is sometimes measured, for example, by means of nasometry, a device that computes the percentage of nasal acoustic energy out of the total energy (oral plus nasal) produced in an utterance. For children with vocal strain, training in vocal hygiene is usually effective in preventing further difficulties, although once polyps or nodules develop, surgical intervention may be necessary. Resonance disorders due to dysmorphology such as cleft palate are typically treated with surgery to correct the malformation, followed by speech-language therapy to address residual errors. For children with resonance disorders of nonanatomical origin, particularly in children with ASD, the voice problem is usually more resistant to treatment.

Language disorder

Diagnostic criteria

DSM-5 defines language disorder as persistent difficulties in the acquisition and use of language across modalities (i.e., spoken, written, sign language, and/or other symbol systems) and may

involve comprehension or production deficits in one or more of the following: (i) vocabulary (word knowledge and use), (ii) sentence structure (the ability to put words and word endings together to form sentences based on the rules of grammar and morphology), (iii) discourse (the ability to use vocabulary and connect sentences to explain or describe a topic or series of events or have a conversation) (American Psychiatric Association, 2013). The particular features of language disorder at each of these levels are detailed in the following sections.

Vocabulary

Children with language disorders are slow to acquire first words. Even when basic vocabulary is learned, children with language disorders often have more limited vocabularies than their peers (McGregor *et al.*, 2013). They tend to rely on nonspecific words (*thingy*) and have difficulty acquiring words with abstract meanings, multiple senses, and figurative uses. In addition, word finding is often affected. Children may even have difficulty retrieving words they know and resort to circumlocutions or imprecise terms such as “whatsit.”

Grammar and Morphology

Children with language disorders are also generally slow to produce first word combinations. While children typically produce their first multi-word utterances at 18–24 months, those with language disorders are often 2½ to 4 years old before word combinations appear. Once sentences are used, children with language disorders produce shorter utterances than their peers throughout the preschool period. They tend to be delayed in their acquisition of grammatical morphology, the markers added on to words that denote meanings such as plural (two books) and possessive forms (Rhea’s book). In English, they have particular difficulty with word endings that mark tense (*helped*) and subject-verb agreement (He runs), use of pronouns (*Me* want ice cream), and often omit auxiliary verbs (*She is* reading; He *can* help), and articles (*the* cake, *a* book; *an* apple). During the school years, children with language disorders continue to use simpler sentences and make more grammatical errors than peers.

Discourse

Three genres of discourse have been studied in children with language disorders: conversation, narrative, and exposition. *Conversational* discourse, the verbal exchange between interlocutors, can be a relative strength for many children with language disorders. By school age, many have mastered enough basic vocabulary and sentence structure to maintain basic conversations, although they may still make errors and are less able to produce complex forms than peers.

Narrative is defined as a primarily monologic discourse, involving the relation of a sequence of events enacted by an agent in which plans and goals play a role (Stein & Glenn, 1979). Narratives typically have a prescribed structure with a conventional beginning, middle, and end, although this structure varies

somewhat from culture to culture. Narrative performance is a strong prognostic indicator of persistent language impairment (Stothard *et al.*, 1998) and academic success (Fey *et al.*, 2004) and is thought to form the bridge between basic oral language and the more literate language styles encountered in print (Westby, 2004).

Expository discourse is the language used to explain, describe, compare, and otherwise present factual material, for example, the type of formal language used in educational settings. Unlike narrative, expository structures are more varied and less reliable as a guide to comprehension. As a result, children with language impairments are particularly weak in this kind of discourse (Nippold *et al.*, 2008). Expository deficits are especially likely to impact academic performance, as most material presented in school, either orally or in writing, makes use of expository structures.

Assessment of language

Deficits in language production are often obvious to adult listeners. Children who mispronounce words, leave words out of sentences, make grammatical errors, or produce very sparse speech are more likely to be noticed by parents and teachers. Other children may experience more subtle deficits in grammatical complexity and language comprehension, which may go unnoticed (Zhang & Tomblin, 2000). There is a high degree of comorbidity between language disorders and a range of other psychiatric and learning conditions, including attention deficits, learning disabilities, and conduct disorders (Im-Bolter & Cohen, 2007), although language impairments in children referred for psychiatric disturbance are frequently undiagnosed, in as many as 40% of cases (Cohen *et al.*, 1998). For these reasons, school-aged children referred for or suspected of psychiatric or learning disorders should be assessed for language disorder.

Preschool assessment

Assessment of language skills in preschoolers typically involves some standardized testing using measures like those in Table 52.1. In addition, a sample of spontaneous speech, collected in a play interaction with a clinician, parent, or peer, can reveal the child’s functional communication skills, as well as the kinds of errors made in natural speech. For children who are extremely reticent to talk, some elicited production tasks may be used, such as allowing the child to “talk” for a puppet, or using a game format such as “I spy” to elicit speech. Parent and teacher reports also provide important information, and several standardized report forms are available including the Vineland Adaptive Behavior Scales (Sparrow *et al.*, 2005) and the Children’s Communication Checklist-2 (Bishop, 2003a).

School-aged assessment

Standardized testing and parent/teacher report are used to identify language disorders and the impact on academic attainment in older children and adolescents. Test scores are often used to

qualify young people for special educational services. Assessment of both language comprehension and production in this case is crucial. In addition, the conversations of young people with language disorder may sound normal to the casual listener, so it is often necessary to use more demanding contexts to assess their spontaneous speech. Samples of narrative language, elicited by asking students to tell a story from a set of pictures or recount a personal or traditional story have been shown to be sensitive to language deficits at school age (Boudreau, 2007). For adolescents, assessment of curriculum-based expository text is an especially relevant area both in terms of the comprehension of factual material and the ability to produce clear, cohesive arguments. Both narrative and expository deficits, when identified, serve as important intervention targets for school-aged students.

Differential diagnosis and common comorbidities

When a child presents with language impairment, the clinician needs to establish whether there are any factors present that may causally influence language difficulties or whether the language impairment is part of a recognized syndrome. Some common co-occurring conditions are considered in the following sections.

Auditory problems

Hearing should always be assessed by an audiologist in a child presenting with language disorder. Universal neonatal hearing screening means that it is unusual to find a previously undetected sensorineural hearing loss in an older child. It is, however, much more common to find conductive hearing losses in young children with language impairment, though the causal relationship with mild-moderate conductive hearing losses is debatable (see Chapter 47). Epidemiological studies have questioned whether otitis media with effusion, which can cause conductive hearing loss of up to 40 dB, is a major etiological factor in language disorder (Paradise *et al.*, 2003). Such prospective studies have revealed that many young children may have prolonged episodes of otitis media and hearing loss with little or no impact on verbal skills.

Diagnosis of central auditory processing deficits (APDs) is also fraught with controversy. One difficulty with diagnosis is that APD is typically assessed using verbal materials (e.g., listening to speech in noise), thus one cannot be sure if poor performance reflects a primary language disorder, or a genuine auditory problem (Moore, 2011). The diagnosis of APD as opposed to a diagnosis of language disorder, ADHD, or dyslexia may depend more on the referral route than the presenting symptoms (Moore *et al.*, 2013). To resolve this difficulty, better assessment methods and inter-disciplinary diagnosis and management are needed to ensure an appropriate diagnosis and management plan.

Low nonverbal cognitive abilities

Both DSM-IV and ICD-10 required a discrepancy between verbal and nonverbal abilities, usually of 1SD, for a diagnosis of

language disorder. However, recent evidence has questioned the validity of this distinction. First, language skills and nonverbal reasoning skills tend to be highly correlated; children with the most severe language disorders also tend to have greater deficits in nonverbal reasoning (Conti-Ramsden *et al.*, 2012). Second, there is no evidence that children with discrepant versus equivalent abilities are etiologically distinct (Bishop, 1994). Finally, there is limited evidence to indicate that lower nonverbal IQ limits response to intensive language intervention (Bowyer-Crane *et al.*, 2011). For these reasons, nonverbal IQ restrictions do not feature in DSM-5 criteria.

Acquired epileptic aphasia (AEA)

Acquired epileptic aphasia (AEA), also known as Landau-Kleffner syndrome, is a rare cause of language disorder which is often misdiagnosed and is associated with epileptiform electroencephalographic abnormalities, though overt seizures are uncommon. The typical presentation is one of language regression after a period of normal language development. Language comprehension is severely affected and deafness may be suspected, but ruled out by a hearing test. Language regression is not a feature of typical language disorder (Pickles *et al.*, 2009), thus evidence of language regression should prompt neurological evaluation for possible AEA. Because children once spoke normally, differential diagnosis will center on selective mutism and ASD (see Chapter 51). These distinctions are further complicated by the fact that although many children with AEA have relatively selective problems with language, a significant minority may have more pervasive developmental and behavioral disturbances (Stefanatos, 2011). Sleep electroencephalogram (EEG) is necessary to document EEG abnormalities and confirm the appropriate diagnosis. Some children, particularly those with onset after age 6, can make a good recovery, but the prognosis for those with preschool onset is often poor. When receptive language deficits persist for more than a few weeks, it is crucial to provide children with alternative modes of communication, such as sign language (Deonna & Roulet-Perez, 2010). While pharmacological interventions may be effective, there is wide variation in response to treatment and a paucity of controlled clinical trials to advocate their widespread use (Stefanatos, 2011).

Specific learning disorders

There is little doubt that language disorder places children at greatly increased risk for reading impairments, contributing to lower educational attainments (Catts *et al.*, 2002; Snowling *et al.*, 2001). The particular profile of literacy skill will depend in part on the child's profile of language impairment; however, children with deficits in language comprehension have particularly poor literacy outcomes. For example, in a longitudinal study of children attending language units at age 7, 67% of children with predominantly expressive language impairments and 88% of children with comprehension deficits had literacy impairments at age 11 (Botting *et al.*, 2006). In addition to

reading impairments, children with language disorders have pronounced difficulties with many aspects of arithmetic, including count sequences and simple computation, though they may have a sound understanding of arithmetic principles (Donlan *et al.*, 2007). Approximately 1/3 of children with language disorder also meet criteria for Developmental Co-ordination Disorder (Flapper & Schoemaker, 2013) (see Chapter 53).

Selective mutism

Selective mutism may be considered when there is a consistent failure to speak in social situations where speaking is expected (e.g., school) despite clear evidence that the child does speak in other situations (e.g., home). Most children with selective mutism also meet criteria for social phobia (Keeton & Budinger, 2012), prompting inclusion of selective mutism among the anxiety disorders in DSM-5 (see Chapter 60). Prevalence rates vary substantially depending on the setting, but suggest that selective mutism is rare, with prevalence estimates of .11% in clinical settings (Carlson *et al.*, 1994) to 2.0% in population surveys (Kopp & Gillberg, 1997). Selective mutism is more common in immigrant and bilingual communities (Elizur & Perednik, 2003).

The fact that children can speak in certain settings suggests that language impairment cannot fully account for the child's reticence to speak. Nevertheless, studies have consistently found that children with selective mutism have lower scores on standardized measures of language relative to peers and children with social anxiety/phobia (Manassis *et al.*, 2003). Indeed, approximately 50% of children with selective mutism meet diagnostic criteria for language disorder in one or more domains (Steinhausen & Juzi, 1996; Kristensen, 2000).

Treatment approaches aim to lower the anxiety that a child has for speaking in certain situations and increase the contexts in which the child may speak comfortably. In general, behavioral treatments, cognitive-behavioral therapy, and/or play therapy will be the first choice of intervention, though at present there are no randomized controlled trials to support any particular treatment approach. Controlled trials have examined pharmacological approaches to manage selective mutism, specifically through the use of SSRIs such as fluoxetine (Dummit *et al.*, 1996; March *et al.*, 2007). Such studies have shown marginal improvements in parent ratings of child anxiety, but many children remain symptomatic after medication. Selective mutism is persistent, with a remission rate of only 58% 13 years after first referral, and high rates of phobia and social anxiety, as well as increased risk for other psychiatric disorder (substance abuse and depression) even in resolved cases (Steinhausen *et al.*, 2006).

Psychiatric disorders, including ADHD

A recent meta-analysis confirmed that language impairment significantly increases risk for social and emotional difficulties in late childhood and adolescence (Yew & O'Kearney, 2013). Children with language disorders are more than 1.5 times more likely to meet criteria for ADHD relative to TD (typically developing) peers and more than twice as likely to experience general

externalizing symptoms. Snowling *et al.* (2006) investigated adolescent outcomes for a clinically referred sample of children with language impairment. The authors reported that diagnoses of ADHD were more common in children with expressive language impairments, whereas social impairments were more common in those with receptive language difficulties.

The high rates of comorbidity observed in language disorder raises obvious questions about causal relationships. Our ability to answer these questions is hampered by a paucity of studies that measure common comorbidities early in development and follow children prospectively. One notable exception is the Ottawa Longitudinal Study, in which language disorder at 5 years of age was one of the strongest predictors of psychiatric outcome at age 12 (Beitchman *et al.*, 1996). However, this study does not elucidate the mechanism of association. The assumption is that language disorder predisposes children to adverse outcome because of the important role language plays in behavior regulation. A child with limited language comprehension may find it challenging to delay gratification, think through another person's motivations or predict the likely consequences of present actions. Another possibility is that the role of language impairment on behavioral outcome is mediated by the experience of academic failure. For example, Tomblin *et al.* (2000) found that risk for psychiatric disturbance was increased when language disorder was accompanied by literacy impairments and was much lower in those children experiencing academic success. The association was less evident when children were assessed prior to learning to read, suggesting that it is the sense of school failure that exacerbates the risk. However, it is also possible that the neurobiological factors that confer risk for language disorder are at least shared with other developmental disorders.

Prevalence

Prevalence figures vary dramatically depending on the diagnostic criteria employed, with estimates ranging from 2% (Weindrich *et al.*, 2000) to 31% (Jessup *et al.*, 2008) of children at school entry. There is no indication that figures vary systematically from country to country; differences in prevalence rates across countries likely reflect variation in diagnostic criteria and availability of services. However, there are few studies regarding the prevalence of language disorder in non-Western European communities.

The most commonly cited prevalence estimate is 7.4% (95% confidence interval 6.3–8.5%), taken from a study of kindergarten children in Iowa (Tomblin *et al.*, 1997). These children had non verbal IQ scores within the normal range, but scored more than 1.25SD below the normative mean on two out of five composite language scores, including receptive and expressive language, vocabulary, sentence grammar, and narrative. Intriguingly, only 29% had been identified by parents or teachers as having language concerns, and only half met the same criteria for language impairment 1 year later. These findings suggest the need to incorporate measures of functional

impact to complement test scores; this may include measures of scholastic achievement or impact on family life and friendships. Moreover, these findings suggest that the features that lead to children being identified as having language concerns may be different to those identified on standardized tests (Bishop & Hayiou-Thomas, 2008). In general, the child starting school with pronounced speech errors or speaking only in short, simple phrases is likely to attract attention, whereas poor comprehension, limited vocabulary, and lack of sophisticated grammar are easier to miss.

As with many other neurodevelopmental disorders, more males than females are affected with language disorder, though again, the rates vary from study to study. For instance, Tomblin *et al.* (1997) reported a gender ratio of 1.33:1 boys to girls in their epidemiological study; by contrast, ratios in clinically referred samples can be as high as 3.8:1 (Robinson, 1991).

Causal models and risk factors

Cognitive theories of language disorder have attempted to explain why language may be disproportionately impaired relative to other developmental achievements. In the past, theories have suggested that the grammatical deficits that characterize language disorder occurred because of a “selective” deficit in dedicated cortical structures that sub-serve language (van der Lely, 2005). However, our recognition that grammatical deficits are rarely “all or nothing,” coupled with our understanding of the developing brain means that a strong version of this hypothesis is no longer tenable. Increasingly, theories attempt to elucidate general cognitive processes that if faulty (or inefficient) could render language acquisition unduly challenging. These theories are outlined below.

Auditory perceptual

Auditory accounts have revealed that children with language disorder have difficulties perceiving sounds that are presented rapidly, are of brief duration, and therefore are not perceptually salient. Such deficits could conceivably lead to problems perceiving and categorizing meaningful phonemic contrasts, leading to problems with language learning. Furthermore, many grammatical contrasts in English are signaled with unstressed phonemes of brief duration occurring in a rapidly changing speech stream; thus a general impairment in temporal or perceptual processing may lead to highly selective impairments in grammatical processing (Joanisse & Seidenberg, 2003). Despite an intuitively attractive account, research has demonstrated that auditory deficits are neither necessary nor sufficient to cause language disorder. Notably, while auditory deficits are more common in children with language disorders, not all children are affected and some children with auditory deficits do not have any language difficulties (Bishop *et al.*, 1999). In addition, intervention studies have indicated that improving auditory skills does not confer improvements to other aspects of language or literacy, calling the causal relationship into question (Cohen *et al.*, 2005; McArthur *et al.*, 2008).

Limited processing capacity

Leonard (1998) argued that perceptual deficits may be more detrimental to language development in the context of a system that has limited capacity to hold information in store while processing perceptually challenging input. Evidence for a limited capacity system stems from poor performance on tasks of working memory and phonological short-term memory (Montgomery *et al.*, 2010). Measures of working memory typically require children to make true/false judgments about simple statements such as “balls are round” and “pumpkins are purple” (the processing component) and then recall the last words of each statement: for example, “round” and “purple” (the capacity component). The argument is that there is a trade-off between processing and capacity, such that when processing demands increase, capacity for recall is reduced and vice versa. On this view, children with language disorders would be expected to have greater difficulty processing sentences of increasing length and complexity, which is the typical profile seen. Similarly, repeating nonwords is thought to index phonological short-term memory, which, in turn, supports the development of vocabulary. Children with language disorders tend to have difficulties repeating nonwords, particularly as syllable length increases (“hampent; blonterstaping”). This in turn is thought to support vocabulary development as acquiring new words depends on the ability to retain novel sound sequences in memory.

While there is little doubt that children with language disorders have substantial verbal memory deficits, the direction of causation is debatable. These theories take a bottom-up view of language processing but there is also evidence for top-down influences on task performance. For example, the more “word-like” nonwords are (i.e., “trumpetine”) the easier they are to remember, suggesting that existing vocabulary knowledge influences nonword repetition abilities. However, even when word-likeness is strictly controlled, there is limited longitudinal evidence that repetition skills predict later vocabulary outcomes (Melby-Lervag *et al.*, 2012). Similarly, verbal working memory tasks are essentially complex language tasks, making poor performance in children with language disorders difficult to interpret (Baird *et al.*, 2010). However, findings of working memory deficits outside the verbal domain lend credence to the view that domain-general cognitive processes contribute to language difficulties (Bavin *et al.*, 2005).

Procedural deficit hypothesis

Ullman and Pierpont (2005) made a distinction between procedural memory systems, which are important for rule-based learning (such as grammar) and declarative memory systems, which underlie knowledge-based learning (such as vocabulary). They hypothesized that language disorder resulted from a primary deficit in procedural memory systems, in the context of relatively intact declarative systems. The appeal of this theory is that it makes explicit connections between brain and behavior, has the potential to explain deficits outside the language system that are also contingent on procedural learning (such as motor

sequencing) and is developmentally attractive in its emphasis on re-organization and compensation. Several recent investigations have noted that children with language disorder are impaired on measures of implicit learning, which tap procedural memory systems (Evans *et al.*, 2009; Lum *et al.*, 2012) and that performance on these learning measures is correlated with language scores (Misyak *et al.*, 2010). However, impairments in learning are not limited to procedural memory systems (Lum *et al.*, 2010) and extend to declarative memory impairments involved in learning facts and associations.

The conclusions from theoretical studies of the cognitive basis of language disorder are that there is unlikely to be a single cognitive factor that can cause the variety of language profiles seen. Instead, multiple cognitive risk factors are present, which act in concert to determine the severity and course of language disorder.

Etiology of language disorders

Genetic basis of language disorder

It is well documented that genetic factors contribute to susceptibility for language disorder. The disorder is highly heritable and shows strong familial aggregation (Conti-Ramsden *et al.*, 2007; see also Chapter 24). Furthermore, twin studies have consistently reported that monozygotic twins have greater concordance rates for language disorder than dizygotic twins, suggesting that much of this aggregation is influenced by genetic factors (Hayiou-Thomas, 2008). There is a strong consensus that the genetic mechanisms at play are multifactorial in nature, consisting of complex interactions between common genetic risk variants and environmental factors (Newbury & Monaco, 2010).

Initial excitement was generated by the discovery that a mutation to the FOXP2 gene resulted in a severe form of verbal dyspraxia and language impairment (Lai *et al.*, 2001). While subsequent research has indicated that such mutations are unlikely to be responsible for the majority of cases of language disorder, there has been considerable interest in the downstream targets of this regulatory gene. In particular, common genetic variants of *CNTNAP2* are associated with poor performance across a range of language measures (Vernes *et al.*, 2008). Intriguingly, this gene has also been implicated in many other neurodevelopmental disorders, pointing to possible shared mechanisms for language impairment across disparate diagnostic categories (Newbury & Monaco, 2010).

Further progress in identifying candidate risk genes may rely on refining clinical phenotypes and identifying particular phenotypic traits that may be heritable across diagnostic boundaries. For example, the *ATP2C2* and *CMIP* genes on chromosome 16 have been identified as having common variants that are associated with performance on tests of nonword repetition (Newbury *et al.*, 2009). The mechanisms by which this association emerges are not currently well understood; however, it is clear that the majority of genes implicated in language disorder are involved in early neurobiological development of brain regions important for language development (Rice, 2012).

An important message to emerge from this line of research is that such genetic influences are not deterministic, but can increase risk for language disorder in probabilistic fashion (see Chapter 24).

Neurobiology

Most children with language disorder do not show obvious brain abnormalities on structural imaging. Instead, like genetics, subtle neurobiological risks act in a probabilistic fashion. Imaging studies of language disorder are few and often yield conflicting results, perhaps due to variations across studies in age of participants, the diagnostic criteria employed and the possible presence of comorbid conditions. Leonard *et al.* (2006) identified seven anatomical variables that increased risk for oral language impairments versus written word decoding difficulties. These included: total size of cerebral hemispheres, asymmetry of the planum temporale, rightward cerebral asymmetry, summed leftward planar and parietal asymmetry, the first Heschl's gyrus on the left, the size of an anomalous second Heschl's gyrus, and rightward cerebellar anterior lobe asymmetry. Individuals with language disorders (and reading comprehension deficits) had strongly negative anatomical risk indices, suggesting smaller cerebral and auditory cortex and more symmetrical brain structures than typically developing peers. Despite the promise of identifying neural signatures of language disorder, Leonard and colleague urge caution in the use of neuroimaging for diagnosis and treatment planning, stating "a negative anatomical risk index is not sufficient for the development of oral language deficits. There is clearly a complex interplay between genetic, environmental, educational, and neurobiological factors in the development of reading and language phenotypes (pp. 3339)."

Environmental factors

There is little evidence that environmental factors alone are sufficient to cause language disorders in all but the most extreme circumstances. However, environmental factors may be implicated in early language delay and may have a role in mediating the developmental course and impact of language disorders on the child's well-being. For example, twin studies have shown that the quality of early mother–children interactions (i.e., the extent to which they elaborate utterances, link their talk to the child's attentional focus, invite the child to comment or take part in the interaction) predicts variation in language abilities at 36 months (Thorpe *et al.*, 2003). Maternal education and socio-economic status have also long been associated with child language development, with children from disadvantaged backgrounds experiencing protracted rates of language acquisition and less success on structured measures of language competence (Letts *et al.*, 2013). Furthermore, recent evidence suggests that neural differences in regional brain volume in the hippocampus and amygdala align with SES status (Noble *et al.*, 2012), possibly resulting from qualitative differences in linguistic input and exposure to stress.

On the other hand, prospective, population studies of risk for language disorder report that although environmental factors may increase risk, the amount of variance explained in language outcome is relatively small (Reilly *et al.* 2010). Furthermore, SES and maternal education levels are at least partially genetically influenced (Oliver *et al.*, 2005). In other words, a mother may have limited educational experience or poor career prospects because of her own language limitations. Nevertheless, early language delay in the context of environmental disadvantage should alert clinicians and educators of the need to monitor linguistic progress carefully.

Distinguishing difference from disorder

In multicultural societies, it can often be difficult to determine whether a child has language disorder, or simply has had limited exposure to the mainstream language or dialect. Standardized testing can complicate this problem, since the words, sentence types, and format of the test may be unfamiliar to child, even when his/her basic language learning capacity is intact. For this reason, other methods of assessment that tap underlying language learning abilities may be used to assess children with English as an additional language. These measures, thought to serve as clinical markers of impairment (Conti-Ramsden, 2003), include repetition of nonwords (which rely on phonological memory and encoding skills thought to underlie word learning), fast mapping, (in which children are taught and asked to retain meanings of nonsense or unfamiliar words), and rapid automatic naming (such as saying all the days of the week in rapid sequence). These more process-oriented tasks can be helpful in determining whether a child has normal language-learning capacity and simply needs more exposure to master English, or needs more focused intervention for language disorder.

Longitudinal outcomes

Long-term prospective studies of children with language disorder converge on very similar findings; language disorder is a remarkably stable diagnosis from school entry (Law *et al.*, 2008; Conti-Ramsden *et al.*, 2012), with the primary difference in language outcomes between children being initial severity. For most aspects of language, growth is linear, with no differences between children with language disorder and their typical peers in rate of growth (Rice, 2013). For aspects of grammar (especially morphosyntax), growth is curvilinear, with a plateau for typical children around the age of four, while children with language disorder lag behind their peers by some 2 years (Rice, 2013).

Educational outcomes are the most vulnerable for children with language disorder; even for those children with apparently resolved language difficulties at age 5, their statutory examination grades are lower than those of age-matched peers (Snowling *et al.*, 2001). Those with persistent language disorder have worse outcome, with nonverbal IQ and literacy skills accounting for independent variance in achievement (Conti-Ramsden & Durkin, 2012). These longitudinal studies have also reported that those who continue into education post-18 are more likely

to follow vocational and training courses rather than pursue University education. Furthermore, young people with language disorder are far more likely than peers to not be in education, employment or training at 19 years of age (Conti-Ramsden & Durkin, 2012).

Early longitudinal studies of boys with severe receptive language disorders at school-age reported a number of adverse social outcomes, including difficulties with independent living, maintaining close romantic relationships and participating in social activities (Howlin *et al.*, 2000). More recent studies report similar, though less severe, social difficulties in adults with language disorder (Whitehouse *et al.*, 2009). All studies report persistent language and literacy difficulties into adulthood. Differences in outcome between cohorts may reflect differences in initial severity, the extent to which language comprehension is affected, and differences in the stability of educational experience, which tends to be more variable for children with language disorder.

Social (pragmatic) communication disorders

The introduction of SPCDs to DSM-5 is in part inspired by the changes to diagnostic criteria for ASD and in part recognition of the fact that many children present in clinic with pronounced difficulties using language for social purposes. As illustrated by the third case history presented in the introduction, these *social communication* difficulties may include a poor understanding of speaker intentions and the verbal and nonverbal cues that signal those intentions, difficulty interpreting the environmental context and societal expectations, and problems integrating these skills with structural aspects of language to achieve successful communication. In addition, children may also have difficulties with *pragmatic* aspects of language, which center more on how children infer meaning or resolve ambiguities by integrating the surrounding language with their prior knowledge and experience.

Nosologies of developmental disorders have included children with social and pragmatic communication deficits for more than 30 years, though the diagnostic status of these children has often been controversial. For instance, Rapin and Allen (1983) first described “semantic-pragmatic deficit syndrome” as a constellation of symptoms including: verbosity, comprehension deficits for connected speech, word finding deficits, atypical word choices, unimpaired phonology and syntax, inadequate conversation skills, speaking aloud to no one in particular, poor topic maintenance, and answering beside the point of a question. Rapin and Allen used this as a descriptive term that was most commonly applied to the communication profiles of children with ASD, but also observed in many other developmental disorders. Bishop and Rosenbloom (1987) considered “semantic-pragmatic disorder” to represent a distinct subgroup of children who occupied a diagnostic space between ASD and specific language impairment. Later research established that semantic deficits did not reliably co-occur with pragmatic

difficulties, and the term “pragmatic language impairment” became more widespread (Bishop, 1998). Typically, these labels have been used to identify deficits in social communication and/or pragmatic language abilities in the context of relatively age appropriate phonology and grammar. However, many children identified with pragmatic deficits using standardized instruments such as the Children’s Communication Checklist (Bishop, 2003a, b) have structural language impairments (Norbury *et al.*, 2004) and pragmatic deficits may also be evident in other neurodevelopmental conditions, such as Williams syndrome (cf. Laws & Bishop, 2004).

As a new disorder, there is limited research concerning the causes, consequences or developmental course of affected children with SPCD. Thus, this section will focus on diagnostic criteria, assessment and differential diagnosis, and consideration of common comorbidities. Although it is now conceptualized as a discrete disorder, it is crucial to bear in mind that social-pragmatic deficits can occur in other neurodevelopmental disorders (e.g., ADHD) and are a key diagnostic feature of ASD.

Diagnostic criteria and limitations

Diagnostic criteria for SPCD include four key aspects of deficit, all of which must be present for diagnosis. These include: using communication for social purposes such as greeting or exchanging information; changing communication to match context or the needs of the listener; following rules for conversation or storytelling, such as turn taking; and understanding what is not explicitly stated and nonliteral or ambiguous meanings of language (American Psychiatric Association, 2013). The criteria go on to specify that these communication deficits occur in the absence of a restricted repertoire of interests and behaviors; in other words children receiving a diagnosis of SPCD must not also meet criteria for ASD, even though the two groups may exhibit similar patterns of social communication behavior. DSM-5 further stipulates that although social and pragmatic difficulties may co-occur with intellectual and language impairments, they should not be caused by those impairments. It is far from clear how that distinction is to be made. Furthermore, as noted earlier, diagnostic criteria for Language Disorder also include deficits in discourse, thus complicating differential diagnosis of these two disorders.

A major challenge for the new diagnosis is that currently, no gold standard, culturally validated instruments exist with which to measure social-pragmatic communication. In part, this is because social communication by definition occurs in dyadic exchanges, making them notoriously difficult to measure in a standardized way. The structure provided by the test situation makes it difficult to capture social communication problems that may arise in everyday situations where the rules of engagement are less explicit and highly dynamic (Volden *et al.*, 2009).

The proposed criteria require that deficits in both conversational skills and pragmatic language (i.e., inferencing and

understanding linguistic ambiguities) are required for diagnosis. There is emerging evidence that these difficulties might dissociate; for instance, experimental measures of inferencing ability and ambiguity resolution have found few differences between individuals with ASD and typically developing peers, providing the individuals with ASD had age-appropriate grammar and vocabulary (Brock *et al.*, 2008; Pijnacker *et al.*, 2009). Thus it would appear that social communication deficits may be evident in children who are indistinguishable from TD peers on measures of pragmatic language functioning.

Autism spectrum disorder and SPCD

A key diagnostic distinction will need to be made between SPCD and ASD and ASD and Communication Disorders more generally (Norbury, 2014). Diagnosis of ASD is fully described in Chapter 51, so here we focus on particular areas of diagnostic difficulty. A major challenge is that many children with ASD have clinically significant language disorders, with recent population studies indicating that almost half of school-aged children with ASD will have language abilities significantly below chronological and mental age expectations (Loucas *et al.*, 2008). In addition, by definition children with ASD also have deficits in social communication, which overlap with diagnostic features of SPCD. There is considerable controversy about the causal relationships between the language and communication deficits that frequently accompany ASD and the core social and behavioral features of the disorder, with some evidence for distinct genetic influences (Happé & Ronald, 2008).

The key differentiation would appear to be the presence of restricted and repetitive interests and behaviors. Previous reports of “pragmatic language impairment” suggested that there were children who experienced substantial pragmatic language deficits but did not meet threshold criteria for restrictive interests and repetitive behaviors (Bishop & Norbury, 2002). However, the majority of children included in the study by Bishop and Norbury (2002) were rated as having speech abnormalities associated with autism, used stereotyped language and a significant minority was reported to have unusual sensory interests. Changes to DSM-5 include the reclassification of stereotyped language as a repetitive behavior, rather than a communication symptom, and include sensory interests. Thus, many of the children studied by Bishop and Norbury (2002) may meet new DSM-5 criteria for ASD. The few studies that have attempted to determine how many children currently diagnosed with ASD would meet new criteria for SPCD have produced mixed results; however, Huerta *et al.* (2012) reported that only 1.5% of their participant pool met social-communication criteria for ASD but did not meet threshold criteria for restrictive and repetitive behaviors (RRIBs).

In the absence of a gold standard assessment of SPCD, we recommend that as a first step, children presenting at child and adolescent mental health or psychiatric services should be evaluated for possible social communication and

pragmatic language impairments. The Children's Communication Checklist-2 (Bishop, 2003a, b) is a commonly used and well-validated parent report instrument that identifies children with social and pragmatic language difficulties in both clinical (Norbury *et al.*, 2004) and community contexts (Ketelaars *et al.*, 2009). The checklist does not provide a categorical diagnosis, but Norbury *et al.* (2004) suggested that negative scores on the Social-Interaction Deviance Composite were more common in those who had social-pragmatic deficits that were out of step with their overall level of language. Children scoring between 0 and 7 were those that tended to have both social-pragmatic and structural (i.e., grammar, vocabulary, and phonological) communication disorders. These children should then be evaluated for ASD: the presence of restricted and repetitive interests and behaviors, rigid routines, unusual sensory interests, and stereotyped language would suggest that a diagnosis of ASD was more appropriate than that of SPCD (see Chapter 51). Those children who do not meet criteria for ASD should be referred to an SLT for a more detailed examination of language and social communication. At present, it is far from clear how Language Disorders and SPCD can be meaningfully distinguished; many children with language impairments struggle with discourse, narrative and pragmatic aspects of language. Therefore, it is best to characterize an individual child's profile of communicative strength and need, and plan intervention to meet those needs, regardless of diagnostic label.

Intervention

General principles of intervention

Intervention goals may vary according to the age and needs of the child. Most randomized controlled trials focus on normalization of the developmental trajectory, as measured by change in scores on standardized assessments. In contrast, many clinicians and educators may focus on teaching discrete new language forms, providing the child with strategies to minimize the impact of communication disorder, or modifying the environment (especially parent-child interaction techniques) in order to improve communication despite speech or language weaknesses. Whatever the ultimate goal, selection of a treatment approach should be based on sound evidence that it is effective, as discussed in Chapter 41.

Speech sound disorders

Williams *et al.* (2010) give an overview of contemporary approaches to intervention which generally fall into three categories: (i) those that focus on the practice, generalization, and maintenance of correct sound production; (ii) those that embed sound production practice in a larger context including sound perception, integration of sounds into grammatical production (producing /s/ as a plural ending rather than as simply a sound), or the understanding of sounds as units within words that can be represented by letters (referred to as *phonological awareness*, often used to improve reading readiness); and (iii) those that

focus on motor movements rather than sounds themselves. Law *et al.* (2004) reported in a meta-analysis that treatments such as these were effective for speech sound disorders, although the number of studies meeting criteria for inclusion in the analysis was small. The one exception is the use of nonspeech oral exercises (e.g., blowing whistles) without speech practice to improve speech production, which is not considered an evidence-based approach. For children with the most severe forms of speech sound disorder, communication often involves the multimodalities, such as signs, pictures, or electronic communication aids, to expand the child's opportunities for successful communication.

Language disorders

There is a dearth of well-designed, randomized controlled trials with which to evaluate interventions for children with clinically significant language disorders. The range of treatments provided by SLTs in the United Kingdom, along with a systematic assessment of the quality of the evidence base supporting each intervention was recently summarized by (Law *et al.*, 2012) and forms a searchable database: <https://www.thecommunicationtrust.org.uk/schools/what-works.aspx>.

The few, randomized controlled trials that exist suggest that interventions which target underlying processes, such as auditory processing, are generally not effective in changing language profiles (Strong *et al.*, 2011). Interventions delivered by highly specialist SLTs that target semantic skills (Ebbels *et al.*, 2012) or particular grammatical forms (Ebbels *et al.*, 2007) in school-aged children with persistent and severe language disorder can be effective, though sample sizes have been small and there is a need for further replication. In contrast to much research in this field, Bowyer-Crane *et al.*, (2008) evaluated interventions that were delivered by trained (and well-supported) teaching assistants. Mainstream school children with poor oral language skills at school entry were randomly allocated to either an oral language intervention that focused on developing vocabulary and narrative skills or a phonology with reading intervention that focused on developing phonological skills and letter-sound correspondences. The children received individual and group sessions three times a week over 20 weeks. In contrast to the phonology with reading intervention, those in the oral language intervention improved significantly on measures of bespoke vocabulary and expressive grammar (see Chapter 41). While these results are highly encouraging, replication in children with more severe language impairments is urgently needed. In general, language comprehension deficits are extremely resistant to change (Boyle *et al.*, 2010) and such children are likely to require on-going support for their language disorder.

Social (pragmatic) communication disorder

There is a paucity of good quality intervention research for children with SPCD, in part hampered by inconsistencies in diagnostic labels, lack of agreement concerning diagnostic criteria and valid instruments for measuring change (Gerber *et al.*,

2012). Adams *et al.* (2012) reported the first randomized controlled trial of the Social Communication Intervention Project, an individualized intervention approach that targets development in three areas: social understanding and social interaction; verbal and nonverbal pragmatic skills, including conversation; and language processing, including narrative, inferencing, and developing word knowledge. In the trial, 88 children with SPCD were randomly assigned to receive the intervention or treatment as usual. The treatment group received 20 sessions of intensive intervention by a highly specialist SLT. No significant treatment effects were observed for the primary outcome measure (the *Clinical Evaluation of Language Fundamentals -4UK*, Semel *et al.*, 2006) or a test of narrative expression. However, significant treatment effects were reported for parent and teacher ratings of conversational competence, pragmatic language skill, and classroom learning.

The study is promising in demonstrating that observable differences in social communication behavior can be achieved after a period of intensive intervention, though for the most part, raters were not blind to the treatment status of individual children. However, study participants were extremely heterogeneous, varying from the 3rd to the 95th centile on all measures of structural language, nonverbal reasoning, and ASD symptomatology, making it difficult to ascertain for whom intervention is most likely to be effective. In addition, the primary outcome measure bore little relationship to the treatment content or treatment aims and was unlikely to be sensitive enough to show change. Given the complexities of social communication and pragmatic language, it is likely that these children will require on-going support as they get older and the complexity of social communication and language increases.

Conclusions

This chapter has focused on children with speech, language, and SPCDs. Such disorders are highly comorbid with other neurodevelopmental disorders and are often present in children referred solely for psychiatric assessment. Furthermore, speech, language, and communication skills are highly predictive of academic and employment outcomes, and critical to the cognitive and social development of children, whatever their primary diagnosis. For that reason, clinicians should be alert to these aspects of development so that appropriate referrals and assessments can be made, in order to facilitate the most appropriate avenues for education and intervention.

Acknowledgments

Disorders of reading, mathematical and motor development

Margaret J. Snowling¹ and Charles Hulme²

¹Department of Experimental Psychology and St John's College, University of Oxford, UK

²Division of Psychology and Language Sciences, University College London, UK

Learning difficulties can occur in the context of global delays in development or where there are more circumscribed deficits in the cognitive processes that underpin learning and school achievement. However, recent conceptualizations of what for many years were considered *specific* or *selective* impairments of reading (dyslexia), writing (dysgraphia) or arithmetic (dyscalculia) now emphasize their frequent co-occurrence with other developmental cognitive disorders including communication impairments, attention disorders (ADHD, attention deficit hyperactivity disorder) and developmental coordination disorder (DCD) (Hulme & Snowling, 2009). Similarly, DSM-5 (American Psychiatric Association, 2013) groups together under a single overarching diagnosis, reading disorders, mathematical disorders, and disorders of written expression as specific learning disorder (SLD). In DSM-5, SLD is placed under the broader category of neurodevelopmental disorders since their impact on neurobiological development is early and probably heavily influenced by genetic risk factors (see Chapter 3). However, as we will argue, the classification of all of these learning difficulties together is not optimal, given what is known of their distinct causes and the need for different treatments to address them.

In this chapter we focus on reading disorders, mathematics disorders, and motor learning disorders, describing their nature and what is known of their causes, before offering advice regarding their management. These disorders are all relatively common and compromise children's learning not only in specific domains but also more generally across the curriculum. Moreover, there is a growing body of evidence of close connections between language skills and educational attainments, at least in part because oral language is the foundation for learning to read which, in turn, provides access to the curriculum. In practice, learning disorders are properly the domain of educators rather than of psychiatrists. Arguably, the new DSM-5 criteria are

more aligned with educational practice than previous versions since the medical model is de-emphasized. According to DSM-5 the diagnosis of SLD requires "difficulties learning and using academic skills...for at least 6 months despite the provision of interventions that target those difficulties." The difficulties should affect one or more of: "word reading, understanding the meaning of what is read, spelling, written expression, number sense, calculation (arithmetic), or mathematical reasoning... The learning difficulties are not better accounted for by intellectual disabilities, uncorrected visual or auditory acuity, other mental or neurological disorders, psychosocial adversity, lack of proficiency in the language of instruction or inadequate educational instruction." As we shall argue, however, this definition ignores important dissociations between disorders (for example, there are many children with reading disorders without mathematics disorder, and vice versa). Considering SLDs as a single category blurs the key distinctions between the different disorders in this category that are crucial to understanding their causes and developing theoretically motivated interventions.

Definitions and diagnosis

Conceptual issues

SLDs can be described at several different levels of explanation. While clinicians tend to focus on their behavioral manifestations, much research examines their distal causes (genetic and environmental) as well as proximal causes at the cognitive level. Hulme and Snowling (2009) outlined a unified framework for considering the causes of developmental disorders of language and learning. Within this framework the development of any given disorder can be seen as depending on the interplay of genetic and environmental risk factors which influence brain development. Critically, however, they argued that it is

important to identify factors at a cognitive level of explanation that play a causal role in the development of a given disorder. For example, in the case of dyslexia, phonological problems (deficits in how speech sounds are represented in the brain) appear to play a major role in the genesis of reading problems; additional cognitive impairments increase the risk (see Figure 53.1). Identifying causal factors at a cognitive level is important, as it leads directly to ideas for treatments that target the underlying deficits responsible for the development of a disorder.

We used the term “causal risk factors” because these risk factors operate probabilistically rather than deterministically to influence development. This means that an individual may be “at risk” but not actually develop a disorder. Here the concept of a cognitive risk factor is useful. By cognitive risk factor we refer to what Bearden and Freimer (2006), referred to as an “endophenotype,” a marker of a disorder which is related to the disorder but present in unaffected as well as affected relatives. Cognitive “endophenotypes” are conceived of as heritable risk factors (or processes) that combine to cause learning disorders but seldom cause diagnosed conditions when they occur in isolation (Bishop, 2006).

A related conceptual issue which confronts the clinician is where to set the boundary between “typical” development and a learning disorder. It is now well established that cognitive and language skills are continuous traits, ranging from weak to strong in the population. It follows that there is no clear cut-off between “normal” and “impaired”; this is perhaps well illustrated by findings from prospective longitudinal studies of children at family risk of dyslexia by virtue of having an affected parent (e.g., Pennington & Lefly, 2001; Snowling *et al.*, 2003). In terms of literacy outcomes, these studies show that children

at family risk do less well in reading and spelling than children from families with no such history. Interestingly, however, there is a step-wise pattern, such that children at family risk who do not fulfill criteria for dyslexia fall midway in terms of their literacy and literacy-related skills between children at family risk who are dyslexic and typical readers. Thus, dyslexia, like other neurodevelopmental disorders, is a dimensional problem, not a clear-cut category.

Related to the issue of cut-offs for “SLDs,” the role of IQ in their definition continues to be debated. Stanovich and Siegel (1994) argued that the core deficit in reading difficulty is a phonological deficit which is sufficient to explain the reading problem and the construct of IQ is therefore not needed. Accordingly the “discrepancy definition” has fallen from favor and DSM-5 makes no explicit reference to this.

A final issue is how to conceptualize the frequent co-occurrence of different SLDs. Many children with dyslexia, for example, have language impairments, symptoms of inattention, and problems of motor coordination (see Snowling, 2009 for a review on changing concepts of dyslexia). It appears that shared genetic risk factors play an important role in explaining the comorbidities that exist between different SLDs.

In summary, key issues for theories of SLDs are the nature of the cognitive mechanisms that are affected and the risk factors that underlie their development.

Disorders of reading and writing

Normal literacy development: a framework

In order to appreciate the causes of disorders of reading and writing, it is important first to consider the process of learning to read, arguably a challenge for all children. According to the Simple View of Reading (Gough & Tunmer, 1986), reading comprehension is the product of decoding (the ability to translate text into speech) and linguistic comprehension. If decoding skills are limited, text comprehension will suffer, and if language skills are weak, a child will read without understanding.

In all alphabetic orthographies (writing systems), reading requires the ability to translate written words into their pronunciations (decoding). An important finding in recent years has been that the predictors of individual differences in learning to read appear to be similar across different alphabetic languages. Alphabetic orthographies differ in the regularity or consistency with which letters in printed words map onto the phonemes in spoken words. English is the least consistent orthography in terms of its spelling-to-sound consistency, French and Danish are intermediate, and other orthographies such as Finnish are very highly consistent. The phonological consistency of an orthography influences how easy it is to learn to read it and learning to read in English is notoriously difficult. Nevertheless, recent evidence indicates that there are three key predictors of individual differences in learning to read that have similar importance in all alphabetic orthographies so far studied:

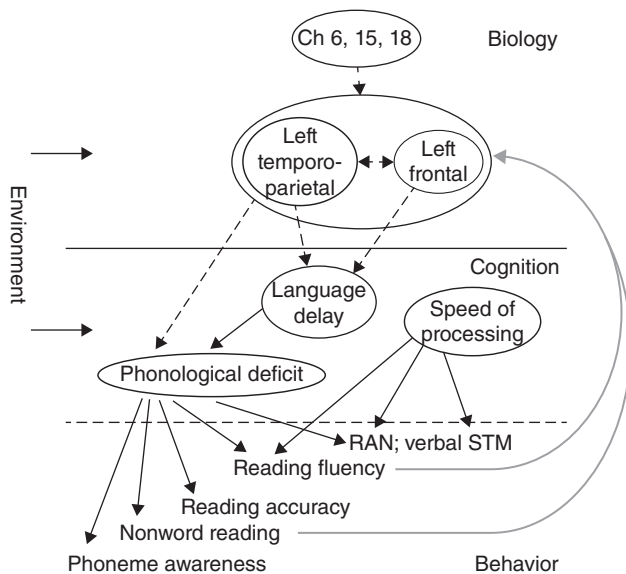

Figure 53.1 Causal model of dyslexia showing biological and cognitive levels of explanation. *Source:* Reproduced with permission of Wiley. *Notes:* Ch-chromosomes; RAN-rapid automatized naming; STM- short term memory.

letter–sound knowledge, phoneme awareness (the ability to reflect on the sound structure of spoken words), and rapid automatized naming (RAN; performance on a test requiring the rapid naming of sets of letters, digits or objects) (Caravolas *et al.*, 2012). In everyday life, children with reading (decoding) difficulties are likely to have had difficulty learning not only letter names and sounds but also numbers and color names. These children have word-finding difficulties and find playing rhyming games or “I-Spy” difficult.

Beyond decoding, the goal of reading is comprehension. Decoding is the first step to comprehension and in the early years of learning to read, children’s resources are directed to decoding. However, to comprehend text, broader language skills, including vocabulary and grammatical skills, are required and individual differences in these skills predict individual differences in reading comprehension after basic decoding accuracy is controlled (e.g., Muter *et al.*, 2004). In addition, higher-level skills, such as inference-making, are important for some aspects of text comprehension (Cain, 2010).

Reading and spelling difficulties

There are two different, commonly occurring forms of reading disorder in children: dyslexia refers to children who have difficulty learning to decode (i.e., in mastering the relationships between the spelling patterns of words and their pronunciations). These children typically read aloud inaccurately and slowly and experience additional problems with spelling. The other major form of reading difficulty is reading comprehension impairment. These children show a contrasting pattern to children with dyslexia in that they can read aloud accurately and fluently but have difficulty understanding what they have read. Children with reading comprehension impairment tend to go unnoticed in the classroom and tend not to come to the attention of clinical or educational services.

Dyslexia

The most widely accepted definition of dyslexia is that of the International Dyslexia Association: “a specific learning disability characterized by difficulties learning to read and write despite adequate cognitive ability, motivation, access to instruction, and intact sensory mechanisms” (Lyon *et al.*, 2003). Building on this conceptualization, a draft DSM-5 definition of “dyslexia” was welcomed by the field when put out for consultation in 2011, though much debate ensued (e.g., Snowling & Hulme, 2012). Unfortunately, the published DSM-5 does not have a separate entry for dyslexia though it is included in the descriptive text; a welcome addition is that problems in reading for meaning are listed separately from problems of word reading (decoding).

Problems of decoding, usually referred to as “dyslexia,” are a bottleneck to reading comprehension; however, the nature of the difficulties change with age. Early on in development, children with dyslexia have difficulty learning letter names and sounds. Later the problem is with “phonics,” literally the translation of print into sound. In adolescence and adulthood, reading may be

accurate but fluency is usually affected and a slow reading rate will affect performance in formal settings such as examinations. Alongside reading difficulties are problems of spelling, initially in producing a phonetically acceptable transcription of target words and later, in English and to a lesser extent in other languages, with the many irregularities of the orthographic system.

Dyslexia is typically diagnosed when a person has severe difficulties with reading accuracy as assessed by a well-standardized test. Given that reading skills have a continuous distribution in the population, the cut-off point for defining “dyslexia” is arbitrary. Estimates of its prevalence in English-speaking countries range from 3% to 10% of school-aged children. In the classic epidemiological studies of Rutter and colleagues (Rutter & Maughan, 2005 for a review), prevalence rates were more than double in an inner city area compared with the Isle of Wight, suggesting that social factors play a key role in risk for reading disability. Boys are more likely to be referred for reading difficulties than girls and this is not simply a matter of referral bias because sex ratios of between 1.5:1 and 3:1 boys to girls have been reported in large-scale community studies (Rutter *et al.*, 2004).

In a recent test standardization of the *York Assessment of Reading for Comprehension* (YARC; Snowling *et al.*, 2009; Stothard *et al.*, 2010) a number of different criteria for the classification of decoding difficulties/dyslexia were tested. Taking account of the prevalence estimates from previous epidemiological surveys, a standard score of 77.5 (1.5 SDs below the mean, around 7% of the population) was taken as indicative of dyslexia and a standard score cut-off of 70 (2 SDs below the mean, around 2% of the population) as severe dyslexia.

From a large subsample of children attending state-funded primary and secondary schools in England, 10.5% of the primary school sample obtained a standard score below 77.5 and 3.9% below 70 in single word reading. Similarly, within the secondary school sample, 8.1% had moderate decoding difficulties and 3.9% severe. More boys than girls were affected at primary school and the proportion of pupils with English as an additional language was significantly higher among poor decoders than in the remainder of the sample. Decoding difficulties were also more common among children from socially deprived areas, underlining the fact that social and cultural factors influence the prevalence of reading difficulties.

Importantly, data from this standardization sample also showed that even when word-level decoding skills are poor, reading comprehension can be intact. Thus, 3.3% of the poor decoders in primary and 4.9% in secondary school showed a significant discrepancy between good reading comprehension (from the prose reading task) and poor reading accuracy (16–41 standard score points), a profile sometimes associated with discrepancy-defined dyslexia.

Typically, the spelling difficulties of people with dyslexia are more severe and more resistant to remediation than their reading difficulties (Romani *et al.*, 2005). Such problems may be seen as a direct consequence of difficulties in mastering

the mappings between orthography (spelling patterns) and phonology (the sounds of words). However, in a minority of cases there are dissociations between reading and spelling skills; some children with adequate reading skills have poor spelling skills and vice versa (Moll & Landerl, 2009).

Problems of reading comprehension

As noted above, reading comprehension impairment is a distinct disorder from dyslexia. Children with reading comprehension impairment can decode and spell words accurately but have problems understanding what they read. Informal observations suggest that these children often read rather quickly and their processing of text is superficial; they do not appear to monitor what they read and may not self-correct, accepting what is termed “a low standard of coherence” for text that they are reading.

Data from the YARC standardization (*op. cit.*) revealed that 5.3% of the primary sample and 5% of the secondary school sample had single word reading which was at the age-expected level with reading comprehension below a standard score of 77.5. Reading comprehension impairment is therefore quite a common disorder which often goes undetected. It has been suggested that the gender imbalance for reading comprehension problems is more even than for decoding difficulties though evidence is sparse.

Many children with reading comprehension impairment have wide-ranging oral language impairments coupled with good phoneme awareness (it is these phonological skills that account for their ability to decode normally). They also experience higher-level language difficulties, including problems with inferencing and with figurative language use, and in text-related processes such as comprehension monitoring and knowledge of story structure (Cain, 2010). Other problems may include poor working memory and problems making inferences and clinically the profile is often seen in combination with ADHD.

Many children with autism spectrum disorders (ASDs) resemble poor comprehenders in that they learn to read well but fail to understand what they read (Brown *et al.*, 2013). The term “hyperlexia” is often used to describe their reading profile. Notwithstanding this, there is considerable variability in the reading profile of children with ASD (Nation *et al.*, 2006; White *et al.*, 2006a) and, just as for typical readers, oral language skills are a good predictor of individual differences in reading in these children. Indeed, in line with the Simple View, impairments in word recognition as well as in oral language comprehension constrain the development of reading comprehension.

Language learning impairments

In recent years, there has been a growing tendency to collapse together disorders of reading (primarily dyslexia) with disorders of speech and language development, reflecting the clinical impression of considerable behavioral overlap between these disorders and their effects on academic performance. Given that reading builds on a foundation in oral language

skills, children who come to school with poorly developed speech and language skills are at high risk of reading disorders (see Chapter 52). The term “language learning impairment” is increasingly used to describe these children who may have varied problems with literacy but who may not fulfill traditional diagnostic criteria. Among this group are children with a history of language delay, children with specific language impairment and children with speech-sound disorders. However, as we shall see, the nature of the risk depends on a number of factors including the pervasiveness and persistence of the speech-language impairment (Pennington & Bishop, 2009; Peterson *et al.*, 2009).

Causal models and risk factors

Phonological deficits in dyslexia

The predominant cognitive explanation of dyslexia is that it arises from a phonological deficit; that is, a problem in processing the speech sounds of spoken words (Vellutino *et al.*, 2004). Phonological skills provide support for verbal short-term memory and more broadly the learning of verbal information. Early manifestations are difficulties with the development of phonological memory, phonological awareness, and phonological learning. These in turn affect the acquisition of letter-knowledge, one of the first signs that a child is at risk of reading problems. Problems with word recognition ensue together with phonological decoding deficits, seen most clearly when attempting to read novel words.

Arguably, the phonological deficit theory does not fully account for the reading problems found in children with dyslexia. Wolf and Bowers (1999) distinguished between disabled readers with deficits in phonological awareness and those with deficits in naming speed measured by RAN (a task requiring the rapid naming of familiar objects, colors, etc.); they also identified a subgroup with deficits in both processes. It is important to understand more fully how RAN is related to the process of learning to read, since performance in RAN is a better marker of who will go on to have reading problems among children with communication impairments than are measures of phonological skill (Bishop *et al.*, 2009).

In recent years, there has been considerable interest in the relationship between RAN and reading (Kirby *et al.*, 2010). One hypothesis is that RAN taps processing speed and this accounts for its relationship particularly with reading fluency. This hypothesis is interesting in view of the fact that slow processing speed is a shared risk factor between dyslexia and the ADHD-inattentive subtype (McGrath *et al.*, 2011); however, the relationship between RAN and learning to read cannot simply be explained in terms of a general processing speed factor. RAN taps the automaticity of naming and, given that object naming is subserved by similar left hemisphere brain circuits to those involved in reading (Price & McCrory, 2005), this leads to the hypothesis that RAN taps a brain circuit involved

in establishing the visual-verbal mappings that are critical to learning to read (Lervåg & Hulme, 2009) and somehow compromised in dyslexia.

Sensory impairments in dyslexia

A large body of research has assessed whether reading difficulties are associated with low-level impairments of sensory and perceptual processing. Investigations have examined putative impairments in visual, auditory, and motor domains as explanations for different manifestations of dyslexia (White *et al.*, 2006b).

Visual deficits

Although most people with reading difficulties have normal visual acuity, there is a raised incidence of abnormalities on psychophysical tasks assessing motion processing which have been related to a deficit within the magnocellular division of the visual system (Lovegrove *et al.*, 1986). However, evidence is mixed and it has been suggested that group differences may be related to uncontrolled differences in IQ (e.g., Hulslander *et al.*, 2004). Some people with dyslexia are also reported to experience visual stress following long periods of reading (sometimes referred to as Meares-Irlen Syndrome or Scotopic Sensitivity); symptoms include reports of text jumping around on the page, headaches and eye strain. However, it has proved difficult to validate these subjective experiences and although the use of colored lenses or filters to reduce visual stress is recommended by some practitioners, there is no evidence for the efficacy of such treatments as a way of improving reading performance.

Auditory deficits

A hypothesis that has attracted considerable research is that the phonological deficit in dyslexia stems from a deficit in basic auditory processing (Tallal, 1980). A recent meta-analysis has shown that frequency discrimination is the auditory processing task most often impaired in dyslexia (Hamäläinen *et al.*, 2013). However, typically only 30–40% of people with dyslexia show auditory impairments, suggesting it may be a co-occurring feature rather than a cause of the disorder.

The direct investigation of speech perception in dyslexia has produced mixed findings. Evidence comes primarily from performance on categorical perception tasks (e.g., identifying synthetic speech sounds as [ka] or [ga]). As a group, children with dyslexia show fuzzy boundaries between different phonemes, constituting a categorical speech perception deficit (but it should be noted that such difficulties are more marked if children have concomitant language impairments (Joanisse *et al.*, 2000; see Chapter 52).

Overall, evidence for the involvement of perceptual problems in dyslexia is equivocal; findings suggest that neither auditory nor visual deficits are necessary or sufficient causes of dyslexia

(Ramus *et al.*, 2003; White *et al.*, 2006b). However, in the absence of longitudinal data, it remains possible that a sensory deficit early in development (that may resolve by the time children are diagnosed as having reading problems) may play a causal role in the etiology of the disorder (Bishop, 2006).

Language delays and difficulties as precursors of reading difficulties

Prospective studies starting in the very early stages of learning to read suggest that children who go on to be poor comprehenders show weaknesses in basic language skills, including weaknesses in vocabulary knowledge, grammar, and syntax from an early age (Catts *et al.*, 2005; Nation *et al.*, 2010). Furthermore, strong evidence for the role of vocabulary impairments in the etiology of reading comprehension comes from a randomized controlled trial of an oral language impairment intervention for poor comprehenders. Gains in these children's reading comprehension skills some 11 months after the intervention ceased were mediated by gains in vocabulary knowledge (Clarke *et al.*, 2011). Similarly, Fricke *et al.* (2013) showed that boosting children's oral language at school entry had positive effects on reading comprehension some 12 months later (Fricke *et al.*, 2013).

Bishop and Snowling (2004) reviewed studies of the relationship between reading and language impairments and proposed that in order to understand these inter-relationships it is important to take a two-dimensional view accounting for both phonological and broader oral language skills (see Figure 53.2). Within this model, the risk of word-level decoding deficits is related to phonological skills (that vary from good to poor) and the risk of reading comprehension deficits is related to language skills beyond phonology (grammar and vocabulary again varying from good to poor). This two-dimensional model has direct implications for the assessment and management of children's reading difficulties and suggests that concerns over whether

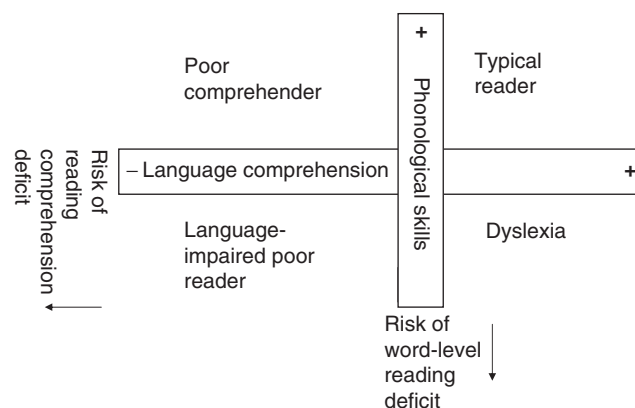

Figure 53.2 A two-dimensional model of the relationship between dyslexia and language impairment. *Source:* Adapted from American Psychological Association.

a particular child fulfills the diagnostic criteria for a specific reading disorder may be of little importance—there are continuous variations in reading skills in the general population and children with either decoding or reading comprehension problems will benefit from appropriate educational interventions that need to be tailored to individual children's needs.

Thus, children who enter school with poorly developed phonological skills (poor phonological awareness, phonological memory, or naming skills) are at risk of decoding difficulties, while children with broader language impairments are at risk of reading comprehension problems. The “type” of reading impairment they display will depend upon their cognitive skills and language weaknesses as well as the interventions they receive, both formally in school and informally in the home environment. Children with clinically diagnosed specific language impairment generally have pervasive reading disorders with both processes affected (see Chapter 52).

Attentional difficulties and reading disorders

It is not unreasonable to think that problems with attention could cause children's reading problems. However, although measures of self-regulation do account for variance in children's early reading skills, many children with ADHD learn to read without difficulty; moreover, medical interventions to improve functioning in ADHD do not lead to improvements in reading skill (Gittelman & Feingold, 1983) (see Chapter 55).

Despite this, dyslexia and ADHD often co-occur and epidemiological findings suggest that their comorbidity is attributable to inattention and not hyperactivity (Carroll *et al.*, 2005); moreover, evidence from twin studies suggests that the disorders are associated with a common risk factor, namely slow processing speed as measured by RAN (McGrath *et al.*, 2011). Beyond dyslexia, it is thought that some children with attention problems have reading comprehension difficulties; although there is limited research evidence it would seem that these are attributable to problems with working memory and the executive control of attention, which is required to build up a coherent memory representation of a text as it is processed.

Etiology of reading difficulties

Genetic basis of dyslexia and related disorders

Prospective studies following the development of children born to parents with dyslexia confirm a heightened risk of literacy impairment in “dyslexic” families (e.g., Snowling *et al.*, 2003; Lyytinen *et al.*, 2006). However, families share environments as well as genes and twin studies can be helpful in disentangling genetic and environmental influences on reading behavior.

Twin studies of dyslexia find that the proportion of variance attributable to genetic factors (heritability) is significant

(Pennington & Olson, 2005; Scerri & Schulte-Korne, 2010) and the heritability of reading difficulties appears to be higher among those with higher IQ (Wadsworth *et al.*, 2010). However, some of the shared genetic variance between twins may be due to gene–environment correlation (Rutter, 2005). For example, the home literacy background provided by more literate parents may foster reading skills and shared reading in the early years has been shown to confer a longer term benefit for children's reading comprehension (Senechal & Lefevre, 2001). Moreover, better readers seek out more literary experiences and print exposure is lower among children with dyslexia than their unaffected siblings (Snowling *et al.*, 2007).

Studies of the molecular basis of genetic influences on reading have used a variety of methods (Grigorenko, 2005, for review). Genetic linkage studies have identified several loci which may contribute to dyslexia, including chromosome regions 15q21, 6p21, 2p, 3p, 18p11, 1p, and Xq27 (Scerri & Schulte-Korne, 2010). Some candidate genes have been mapped within these linkage regions, including DCDC2 and KIAA0319 on 6p and DYX1C1 on 15q21, which have all been replicated in independent studies (Paracchini, 2011). It is important to remember, however, that these genetic influences are associated with reading across the population and are not dyslexia-specific. Moreover, all the genes involved have small effects; much current research is directed toward trying to understand the impact of these genes on neurodevelopment.

To date, there is no comparable analysis of reading comprehension difficulties. However, work on the genetic basis of specific language impairment suggesting linkage to chromosomes 16 and 18 is likely to be relevant (Monaco, 2007).

Brain bases of dyslexia

The majority of children with specific reading difficulties do not show any structural brain abnormalities, but early neurodevelopmental abnormalities appear to be involved (Galaburda, 1994).

Findings from functional brain-imaging studies indicate that children and adults with dyslexia typically show less activity than controls in left hemisphere reading networks in temporo-parietal cortex when reading (Shaywitz *et al.*, 2004; Price & McCrory, 2005; Richlan, 2012). Moreover, a recent study suggested that greater right prefrontal activation during a phonological reading task (in turn indicative of better white-matter organization) significantly predicted reading outcomes in dyslexia whereas behavioral measures including tests of reading and language did not. Together the findings identify right prefrontal brain mechanisms that may be critical for reading improvement in dyslexia and may be indicative of the ability to develop compensatory mechanisms (Hoeft *et al.*, 2011). However, at present, such information cannot inform treatment of reading difficulties.

Social and environmental influences on reading development and disorder

Home and school background

It is important not to overlook the critical role of the environment in shaping a child's reading development (Phillips & Lonigan, 2005). Evidence indicates that reading disorders show a strong social gradient that is not entirely attributable to differences in phonological skills or general intellectual abilities (Hecht *et al.*, 2000) and poor readers often come from large families, where later-born children may face delays in language development. One aspect of delayed language development is poor vocabulary, which in turn appears to be related to later developing deficits in phoneme awareness (Carroll *et al.*, 2003). Parental educational level is also an influence on literacy skills, which may reflect differences in the amount and quality of literacy-related activities delivered to children at home (Whitehurst & Lonigan, 1998). More specifically, parental teaching of print concepts has been found to be associated with better reading outcomes early in development when decoding is primary, whereas shared reading as a literary experience appears more important later for reading comprehension (Senechal & Lefevre, 2001).

Traditional definitions of dyslexia excluded children whose reading failure was caused by "inadequate opportunity to learn," but how to interpret this is unclear. Comparisons of children from the same catchment area attending different schools have emphasized that schooling can make a substantial difference to reading achievement (Rutter & Maughan, 2002). Equally, school experience can differ markedly between good and poor readers.

Cross-linguistic manifestations of reading disorders

Aside from the home and school environment, an important macro-environmental influence on reading development is the language in which a child learns. The reading and spelling symptoms of dyslexia vary across orthographies; in languages such as German or Finnish which are more regular than English, reading difficulties are identified by slow rates of reading (few reading errors occur), whereas in English, poor reading and spelling accuracy are the primary behavioral markers of dyslexia. Recent research in scripts with large character sets indicates that learning the basic symbol set is protracted and poor readers have difficulty in mastering it (Nag & Snowling, 2010; for akshara in an alphasyllabic script; McBride-Chang *et al.*, 2011 for Chinese). Parents may be concerned about the literacy skills of children with bilingual or multilingual backgrounds. The evidence available suggests that learning to decode in one language facilitates learning in a second language (at least if they are both alphabetic); however, reading comprehension depends upon the children having proficient language skills in the language they read in (Melby-Lervåg & Lervåg, 2014).

Summary

As might be expected for a complex trait such as reading, the etiology of reading disorders is varied and depends on both genetic and environmental factors. It is critical to distinguish between problems with decoding and problems of reading comprehension. Some children carry a genetic risk of dyslexia but whether or not they are classified as dyslexic depends upon the particular language and school context in which they learn and the other skills (or deficits) they bring to the task of reading. In keeping with this, there is currently a move away from single-deficit toward multi-factorial models that explain the nature and causes of dyslexia. This point was first made forcibly by Pennington (2006) who argued that the etiology of complex disorders, such as dyslexia, involves the interaction of multiple risk and protective factors, genetic or environmental, which alter the development of cognitive function and thereby produce the behavioral symptoms that define these disorders. It follows from this that comorbidity between disorders is to be expected because of shared risk factors.

Problems of numeracy

Problems in learning basic mathematical skills (Mathematics Disorder) is another form of SLD that is relatively common. In order to understand such problems it is important to first briefly consider evidence about the typical development of these skills.

The typical development of number skills and arithmetic

There is evidence from studies of preverbal human infants and nonhuman animals that some form of "approximate number sense" exists in the absence of language. For example, 6-month-old infants can discriminate between arrays of 16 versus 32 dots, but not between arrays of 16 versus 24 dots (Xu & Spelke, 2000). It has been suggested that this approximate number sense forms the basis of more refined forms of number representation seen in older children, though this proposal remains controversial.

One critical skill for mastering basic arithmetic skills is counting. The ability to count typically begins to develop in the preschool years but shows an extended period of development over the early school years (5–10 years of age) with the accuracy and speed of counting showing steady improvements with age. Counting depends upon understanding a set of abstract "how to count" principles (Gelman & Gallistel, 1978) but also requires verbal skills. Once at school, children are taught arithmetic formally, and master (in roughly the following order) addition (beginning with single-digit addition before moving on to deal with multidigit numbers), subtraction, multiplication, and

division. Usually, fractions, proportions, and percentages are introduced after arithmetical operations dealing with whole numbers have been mastered.

Definition, classification, and prevalence of mathematical difficulties

DSM-IV identified a condition referred to as Mathematics Disorder, but as noted earlier, DSM-5 conflates this condition with a range of other educational difficulties, under the category of SLDs. An alternative term that is sometimes used for this disorder is dyscalculia. While comorbidities between mathematics disorder and reading and other disorders are certainly common, it seems a backward step to not separate such different problems which have separable cognitive causes and require different forms of educational interventions (see Chapter 41).

Mathematics disorder has typically been defined as a difficulty in learning mathematics which is out of line with other aspects of a child's development (particularly IQ). In practice, most studies of this disorder have focussed on children in the 7- to 11-year-old range, and the problems leading to a diagnosis of mathematics disorder are difficulties with basic arithmetic skills, rather than difficulties with higher-level mathematical skills such as algebra and geometry.

The incidence of mathematics difficulties is less well documented than for reading difficulties. Perhaps the best estimates of prevalence come from a UK study by Lewis *et al.* (1994) which used a simple cut-off approach to defining difficulties among 9- to 10-year-old children. They reported that only 1.3% of children showed specific difficulty in maths (standard score less than 85) in the presence of normal nonverbal ability and reading (at or above a standard score of 90 on both). However, another 2.3% had both reading and maths problems defined in an analogous way. This study reported an equal incidence of maths difficulties in boys and girls, in contrast to the higher incidence of reading difficulties among boys that they (and other studies) reported.

The behavioral profile of children with mathematics disorder

The typical profile of children with mathematics disorder is that they show patterns of performance on simple arithmetic tasks that are characteristic of much younger, typically developing children. The pattern of problems with arithmetic seen in such children will vary as a function of age. Children with arithmetic difficulties initially experience problems learning to count. Once the formal teaching of arithmetic begins, these children show delays in mastering addition and subtraction, and they may tend to rely on the "count-on" strategy when solving simple addition problems for longer than typically developing children (Geary, 2004).

With more complex addition problems, children with mathematics disorder tend to guess more often and less accurately than their peers (Geary *et al.*, 2004). Although they use the same strategies as age-matched controls, they differ in the speed and skill of strategy execution, can retrieve fewer number facts from memory, are poor at monitoring their counting, and poor at detecting computational errors (Geary, 2004). It is plausible to argue that problems in counting lead children with mathematics disorder to produce incorrect answers to arithmetic problems frequently, and these errors in turn may lead to the creation of inaccurate representations for the solutions to problems that are stored in memory.

Cognitive explanations of arithmetic difficulties

There has been a growing interest in the last 10 years in trying to identify the cognitive impairments that cause mathematics disorder. Four areas of difficulty have been suggested: problems with number (magnitude) representation; counting problems; number–fact storage problems, and working memory/executive impairments. We will consider each in turn.

Deficits in number (magnitude) representation

Dehaene (1997) has argued that the basis of numerical cognition is an innate "approximate number sense" (ANS)—a preverbal system involving the ability to understand physical magnitudes and numerical quantities. It has been suggested that the ANS is a basic building block for the later cultural construction of abstract, symbolic number concepts which in turn underpin the development of arithmetic skills. In this view, a deficit in the ANS may be a basic cause of the problems in learning arithmetic seen in children with mathematics disorder.

The ANS is a system that serves to represent magnitudes and numerosities in an abstract analog code. The precision of coding within the ANS is typically assessed by tasks that measure the accuracy and speed of discriminating groups of objects on the basis of their numerosity (Piazza *et al.*, 2010). The difficulty of such discriminations varies in proportion to the ratio between the numerosities to be judged. The precision of ANS coding increases with age: 6-month-old infants can distinguish 8 from 16 objects but not 8 from 12 objects, while most adults can distinguish 9 from 10 objects without counting. There are also reported to be large individual differences in the precision of the ANS within an age group (Castronovo & Göbel, 2012).

If variations in the precision of coding within the ANS are a cause of the difficulties with arithmetic seen in Mathematics Disorder, we would expect variations in the functioning of this system to predict individual differences in arithmetic performance. Most of the evidence relevant to this idea comes from concurrent studies which have yielded mixed findings (e.g., Sasanguie *et al.*, 2012).

Such concurrent correlations are inherently ambiguous with regard to questions of cause and effect, and longitudinal studies potentially provide more powerful evidence. Here again however, evidence is at best mixed, with some studies reporting significant longitudinal correlations between earlier ANS skills and later arithmetic performance (Mazzocco *et al.*, 2011; Libertus *et al.*, 2013) while other studies have failed to find such an effect (Fuhs & McNeil, 2013). Furthermore, it may be that learning arithmetic leads to improvements in the precision of coding in the ANS and in line with this possibility, Piazza *et al.* (2013) found that the precision of coding in the ANS was greater in participants who had received formal education compared with those who had not.

There is evidence that children with arithmetic problems are less accurate than age-matched control children at comparing the magnitudes represented by Arabic digits (Landerl *et al.*, 2004; Rouselle & Noel, 2007). However, in two of these studies, the children with mathematics disorder were just as fast and accurate in making physical size judgements or judging numerosities. Hence, these children's difficulties in comparing the magnitudes of digits do not seem to align with a problem with the functioning of an ANS system, and may instead reflect difficulties in learning associations between verbal symbols and magnitudes.

In summary, while deficits in an approximate number sense system are a possible cause of problems learning arithmetic, to date evidence for this suggestion is at best weak.

Deficits in counting

Counting is a fundamental skill for learning to perform arithmetic. Learning basic addition usually begins with children counting to compute the answer (What is $4 + 2$? Response 4...5...6 (the answer)). It is well established that children with mathematics disorder find learning to count hard and these children frequently make errors when counting arrays of objects. Furthermore counting is typically slower in children with mathematics disorder than in age-matched control children (Passolunghi & Siegel, 2001; Landerl *et al.*, 2004). It appears that problems in learning to count are a likely contributory cause to the problems seen in children with mathematics disorder, though longitudinal studies of the relationship between early counting skills and later arithmetic skills are badly needed.

Number fact storage deficits

Children with mathematics disorder have problems storing number bonds in memory (remembering that $4 + 2 = 6$). This is demonstrated by the observation that when presented with relatively simple sums they are likely to calculate answers by counting rather than retrieving the answer directly from memory. As noted earlier, one interpretation of this effect is that repeated errors in calculating the answers to simple problems result in "noisy" information being stored in memory. It is also possible, however, that these children have specific problems in storing numerical information in long-term memory. Evidence from acquired disorders of arithmetic following brain

damage suggests that number facts may be stored in a partially independent system, from verbal long-term memory. It remains a possibility that this memory system fails to develop adequately in children with mathematics disorder (see Hulme & Snowling, 2009).

Working memory deficits

The term "working memory" refers to the ability to store and process information at the same time (Melby-Lervåg & Hulme, 2013). During calculation, subcomponents of an arithmetic problem must be held in temporary storage while processing proceeds. With multidigit problems, it is necessary to monitor the calculation process, to inhibit numbers from the initial calculation and to hold in mind the products of different steps in the calculation. Thus, arithmetic skills carry both simple and complex working memory demands and also tap executive function. It is therefore not surprising that working memory deficits are associated with arithmetic difficulties. Children with arithmetic difficulties perform poorly on complex working memory tasks, such as backward digit span (which has an executive component) and counting span, but typically perform normally on simple tests of verbal short-term or phonological memory unless the task has a numerical component.

Executive deficits

A body of evidence implicates executive deficits in arithmetic disability (Hulme & Snowling, 2009 for review). These include impairments on the "Trail Making" task where children were required to connect alternating sequences of numbers and letters (e.g., 1-A, 2-B) or numbers and colors (e.g., 1-yellow, 1-pink, 2-yellow, 2-pink) and on several aspects of the Wisconsin Card Sorting Test, notably perseveration. It has been proposed that such difficulties impair their ability to shift psychological set, plan action, and judge the reasonableness of answers—all skills that are involved in mathematics. However, such difficulties may be attributable to comorbidities with other disorders (e.g., ADHD) that have not been controlled for in these studies.

Summary

To summarize, the nature of mathematics disorder is much less well understood than reading difficulties, and this reflects the fact that much less is known about the mechanisms of mathematical skills and their development. Mathematical skills depend upon a complex interplay between nonverbal and verbal cognitive systems, and mathematical skills are arguably more diverse and more complex than reading skills. It seems likely from a cognitive perspective that mathematical difficulties result from a number of underlying cognitive deficits. Possible deficits include impairments in an approximate number sense system located in parietal brain areas, as well as verbal systems that interact with this system. Further progress in this area is likely

to depend upon longitudinal studies that attempt to focus on more well-defined arithmetical skills.

Etiology of mathematics disorder

Genetic effects

There is evidence indicating substantial genetic and environmental influences on the development of mathematical skills generally, and more specifically on the development of mathematics difficulties. There is good evidence that mathematical difficulties tend to run in families but this may reflect either shared environment or genetic effects. In a large-scale UK twin study, Kovas *et al.* (2005) found evidence for substantial heritability for normal variations in mathematical skills. There were substantial overlaps between the genes responsible for arithmetic and general intelligence, and arithmetic and reading, though the degree of overlap was far from perfect, suggesting that there are specific genetic effects on the development of arithmetic skills.

There are very few studies that have directly assessed possible genetic influences on mathematical difficulties (as opposed to normal variations in mathematical skills). In a study with a large sample (Oliver *et al.*, 2004), the heritability of mathematical difficulties was assessed by selecting children in the bottom 15% of the population on teacher ratings of children's mathematical abilities. This study yielded a high group heritability estimate for mathematical difficulties of 0.65. These results are compatible with the same genetic influences operating to produce the group deficits in mathematics as well as the range of individual differences in mathematical skills observed within the population as a whole (Plomin & Kovas, 2005; see Chapter 24). It has also been reported that the comorbidity between mathematical and reading difficulties is in part due to common genetic influences operating on both disorders (Knopik *et al.*, 1997).

Brain bases of arithmetic disorders

The neural substrate of the ANS system appears to depend critically upon bilateral areas of the horizontal intra-parietal sulcus (HIPS). Dehaene *et al.* (2003) have proposed that there are three parietal circuits for numerical processing. Problems in the development of such brain systems may be fundamental to the problems observed in children with mathematical difficulties, though as yet direct evidence for this is lacking. Consistent with the idea of mathematical difficulties being associated with parietal dysfunction, Isaacs *et al.* (2001) reported a specific reduction in gray matter in the left HIPS in a group of adolescents with mathematical difficulties (without reading problems) who had been born prematurely, compared to a control group without mathematical difficulties who had been born equally prematurely. This difference in the left HIPS was only found for children with problems with calculation, and not for another group of children who had problems with mathematical reasoning. Also, several studies have shown parietal deficits in Turner syndrome, a syndrome associated with arithmetic deficits.

Developmental coordination disorder (DCD)

Nature, classification, and incidence of DCD

DCD, sometimes referred to as "developmental dyspraxia," is a disorder of motor skill learning. An earlier term used to refer to this group is developmental apraxia and agnosia, capturing the central role of perceptual disorders in the clinical profile of these children. DCD is included here because problems with motor skills can adversely affect children's educational achievements and self-esteem.

The criterion for diagnosis of DCD from DSM-5 is as follows: "Motor performance that is substantially below expected levels, given the person's chronologic age and previous opportunities for skill acquisition. The poor motor performance may manifest as coordination problems, poor balance, clumsiness, dropping or bumping into things; marked delays in achieving developmental motor milestones (e.g., walking, crawling, sitting) or in the acquisition of basic motor skills (e.g., catching, throwing, kicking, running, jumping, hopping, cutting, coloring, printing, writing)." Additionally, such difficulties need to be of a severity such that they interfere with "daily living or academic achievement" and they should not be due to a general medical condition (e.g., cerebral palsy, hemiplegia, or muscular dystrophy). It is notable that this definition has moved away from specifying a discrepancy between motor skills and IQ (as was the case in DSM-IV). A diagnosis of DCD should preferably be made using a standardized test of motor skill though parent and teacher rating scales exist that are also useful (Wilson, 2005; Chambers & Sugden, 2006). DCD is commonly comorbid with other developmental disorders (see Hulme & Snowling, 2009) such as language impairment (Hill, 2001) and autism and the overlap with attention problems is high (Gillberg, 1999).

Population estimates of the incidence of DCD vary widely (from 5% to 18%) and these estimates depend both on the tests and the cut-offs used for diagnosis. It has been reported that there is a ratio of at least two boys to each girl with DCD (Wright & Sugden, 1996), though data on gender ratios may be hard to interpret because some of the tasks used to assess motor skills are gender-biased (e.g., throwing a ball) and there is little agreement among professionals about diagnostic criteria. The symptoms of DCD can vary considerably and may include gross motor difficulties, such as problems running, hopping, jumping, catching a ball and balancing, and fine motor difficulties including a lack of manual dexterity, difficulty in doing up buttons and laces, in dressing and in using eating utensils. Speech-motor skills can be affected and problems of pencil control are widespread.

A mistaken view is that children with DCD grow out of their clumsiness; follow-up studies are rare but evidence suggests that such children remain less physically competent throughout adolescence (Gillberg & Gillberg, 1989) and the difficulties they have at secondary school include problems with handwriting and the presentation of work, and difficulties in science, art, design, and technology (Losse *et al.*, 1991). However, the

coupling between motor impairments and academic achievement may not be causal and is likely mediated by comorbidities and/or psychosocial problems.

Explanations of developmental coordination disorder

The normal development of motor skills appears to be heavily dependent on maturational changes which nevertheless are subject to environmental influences (particularly with respect to the timing of motor skill development). Perceptual processes appear to play a critical role in adult motor skills and in their development. The control of movements depends upon inputs from the vestibular system (responsible for balance), proprioception (awareness of the positions of body parts), and kinaesthesia (awareness of body movements). Most crucially, however, most motor actions depend on visual information to initiate and guide movements. It has been proposed that guidance of our movements in space depends upon a sensorimotor map that serves to translate visually perceived locations to spatially appropriate action patterns (Held & Hein, 1963). Deficits in this sensorimotor map have been proposed as a unifying cognitive explanation for many of the problems seen in motor control in children with DCD (see Hulme & Snowling, 2009). Problems in the development of such a system may depend upon a range of perceptual problems, but most prominently deficits in visual perception.

Visual perceptual deficits

Strong evidence exists for an association between visual perceptual problems and motor disorders (in the absence of problems with visual acuity), with the greatest deficiency being observed in visuo-spatial tasks, regardless of whether they have a motor component (see Hulme & Snowling, 2009). It could be argued that a deficit in the visual perception of spatial information will inevitably lead to problems in the guidance of movements and problems in “calibrating” and “re-calibrating” the sensorimotor map during development. Clinically, occupational therapists often use visual perceptual training programs with these children (Cermak & Larkin, 2002).

Balance and postural control

More proximal causes of DCD have been proposed in balance and postural control, movement planning and preparation, and execution and feedback processes (Geuze, 2005). In addition, limitations of memory and attention and reduced muscle strength may play a role. It should be noted that in principle some of these difficulties might arise as a consequence of the perceptual impairments discussed above.

Etiology

There is evidence that low birth weight or prematurity increases the risk of developing DCD (Jongmans *et al.*, 1996), suggesting

links with neurodevelopmental immaturity. Furthermore, a careful clinical examination may reveal neurological symptoms such as choreiform movements of unsupported limbs in such children. More generally, the comorbidity of DCD with impairments of reading and language, as well as with ADHD and autism spectrum disorder, suggests shared genetic risk with these other developmental disorders (see Chapter 3). Behavior genetic evidence (Martin *et al.*, 2006) indicates a substantial heritable influence on both DCD and ADHD, as well as a substantial shared genetic influence on both disorders.

Longitudinal outcome of learning disorders

Relatively little is known about the adolescent and adult outcomes of children with SLDs although some evidence is available with regard to dyslexia. For some individuals, difficulties of learning in school leads to a downward spiral of disengagement, low attainment, and poor career prospects, with associated mental health issues. It is however, not known how common this clinical picture is. Here we summarize briefly the current state of knowledge, with a particular emphasis on reading disorders.

Cognitive and educational outcomes

There is stability in literacy skills from an early stage and although there has been discussion of “compensated” dyslexia, most poor readers continue to have problems of reading fluency, spelling, and phonological awareness into adulthood (Bruck, 1992). Furthermore it is likely that the effects of reduced reading experience are cumulative, causing differences in reading competence to become magnified over time. A follow-up of the literacy outcomes of preschool children with speech-language impairments at school-leaving age showed that educational achievements were strongly predicted by literacy skills (Snowling *et al.*, 2006), underlining the importance of literacy to later attainments across the curriculum. In a long-term follow-up from the Isle of Wight Study, Maughan *et al.* (2009) reported that poor reading at school-leaving age was associated with a correlation of over 0.9 between spelling in adolescence and spelling at age 46 years. These individuals had typically spent careers in jobs which did not require literacy skills.

Psychosocial and mental health outcomes

There is a dearth of information regarding the psychosocial outcomes of children with SLDs. It is generally thought that learning disorders have a negative impact on emotional and behavioral development and an association between dyslexia and self-esteem has been reported. Snowling *et al.* (2007) reported that adolescents with dyslexia were rated by parents as having more emotional difficulties (but not social difficulties or conduct problems) than children at family risk without dyslexia. The same adolescents perceived themselves to be less academic

than their peers (which of course was true) but no different in terms of social or athletic ability.

There is evidence of a link between reading difficulties and both conduct problems (Maughan *et al.*, 1996) and depression and anxiety (Maughan *et al.*, 2003). However, the processes responsible for these outcomes are not understood and comorbidities likely complicate the picture. For example, disruptive behavior at school may be the result of attention problems which are comorbid with poor reading and may interfere generally with school engagement. Maughan *et al.* (1996) followed 127 poor readers from the age of 10 years into early adulthood. There was a tendency for reading difficulties to be associated with poor attention and over-activity, which in turn placed poor readers at risk of behavior problems. However, behavior problems at 14 years reflected earlier behavior problems rather than reading difficulties and social adversity was found to increase the risk of antisocial behavior among girls but not among boys (for whom increased rates of offending were associated with poor school attendance).

As young adults, about 25% of this sample remained severely impaired in reading (Maughan & Hagell, 1996). Nonetheless, relatively positive self-reports suggested that many had gained employment in which there were restricted literacy demands and their reading problems were no longer of functional significance. In the majority of areas, those with a history of specific reading difficulties were functioning comparably to peers. However, young women with a history of specific reading retardation were at increased risk of psychiatric disorder, particularly depression, possibly related to a high rate of relationship breakdown. Male poor readers, in contrast, had more difficulty in gaining independence. However, these difficulties were the consequence of comorbid difficulties with peer relationships rather than reading problems.

In a study of 289 9- to 15-year-olds identified as having specific literacy difficulties from a representative sample of some 5000 UK children, Carroll *et al.* (2003) reported that children with reading difficulties are at increased risk of attention problems, conduct disorder, anxiety disorders, and depressed mood. However, they argued that the mediating mechanisms differ. The association between literacy difficulties and behavior problems was mediated by inattention (rather than hyperactivity), whereas the link with heightened levels of anxiety was direct. A similar conclusion was reached from a twin study of literacy difficulties by Willcutt and Pennington (2000). These investigators reported an increased risk of attention and conduct difficulties in probands as well as co-twins; however, anxiety was reported only in those with reading difficulties, suggesting that such difficulties may arise as the result of stresses associated with educational difficulties. Regarding the link between poor reading and low mood, Willcutt and Pennington (2000) reported heightened levels of depression in girls, mediated by ADHD, whereas Carroll *et al.* (2003) found that self-reported low mood was more common in boys than girls, and primarily in the 11- to 12-year-old age group.

Other learning difficulties

Relatively little attention has been paid to the outcomes of specific learning difficulties other than reading. Some evidence suggests that the psychosocial outcomes of children with DCD can be reasonably good, with low self-esteem restricted to the motor domain (Losse *et al.*, 1991). However, Skinner and Piek (2001) found that children and adolescents with significant movement problems had lower self-worth and higher levels of anxiety than controls. Similarly, Dewey *et al.* (2002) reported that children with DCD experienced social problems and displayed a relatively high level of somatic complaints based on parent report.

Although it is generally believed that SLDs can cause psychosocial problems, the evidence for this view is sparse. A reasonable conclusion is that the majority of children with specific difficulties in literacy and numeracy are relatively free of mental health problems but there may be more variability among those with motor disorders, perhaps because of the comorbidities associated with this condition.

Clinical implications

Children with SLDs will rarely be referred to child psychiatrists unless such difficulties have contributed to emotional or behavioral difficulties. However, it may be easy to miss a specific learning difficulty in a child with a mental health problem. Here we outline an approach to assessment, beginning with a set of questions a clinician might ask about educational progress before outlining the components of a comprehensive assessment battery.

In DSM-5, SLD is diagnosed via clinical review of an individual's developmental, medical, educational, and family history, reports of test scores and teacher observations, and response to academic interventions. Risk signs evident from the history include late talking, speech difficulties, delayed motor development, and a slow start in learning the names of colors, letters, and numbers. A family history of reading or maths difficulties, or an affected older sibling, is a noteworthy sign. In the case of DCD, tell-tale signs will include significant problems with gross and fine motor coordination and often balance. Speech-motor skills are sometimes, but not usually, affected.

Most clinicians will have access to educational data and school reports and a simple questionnaire asking for teacher ratings of reading, spelling, and maths can be very helpful. Teacher ratings of children's progress are available in UK schools and have been validated against objective tests (Snowling *et al.*, 2011). At the time of writing, parents in England also have access to their child's scores on a statutory Phonics Screening Check given to all Year 1 (6-year-old) children. For school-age children there are easily accessible standardized questionnaires for completion by parents and teachers for assessing DCD (e.g., *Developmental Coordination Disorder Questionnaire*; Green *et al.*, 2005). The *Strengths and Difficulties Questionnaire* (Goodman, 1997) can

provide information on attention control. Documentation of whether a child's additional learning needs are recognized, the history of interventions received including speech and language therapy, and any special support currently in place is important. Some simple tests may also aid in determining whether the child needs further assessment. For dyslexia, these might include asking the child to repeat some difficult words, such as "preliminary," "philosophical," and "statistical," and some nonwords ("bagmivishent," "turnadulatical") to assess whether they do less well than might be expected for their age; and to complete a short reading test, such as the *Test of Word Reading Efficiency* (TOWRE-2; Wagner *et al.*, 2011) which takes only 90 seconds and provides a very useful tool. Together, the findings will enable the clinical team to decide:

- (i) Does the child's school have sufficient resources to support the child without further educational assessment?
- (ii) Should the child be referred directly to a specialist teacher who can offer tuition?
- (iii) Should the child be referred for a comprehensive educational assessment (see below)?
- (iv) Is there need for additional assessment, for example, referral to a speech and language therapist (see Chapter 52) or in the case of motor incoordination, to a physiotherapist or occupational therapist?

Diagnostic assessment

If a referred child has significant academic difficulties or has dyspraxic tendencies affecting physical coordination and handwriting, the most appropriate strategy is to refer this child to an agency within the school system for assessment.

Ideally a psychological assessment should be hypothesis-driven (see Chapter 34). In practice, to provide a comprehensive picture of a child's learning problems and teaching needs, it should include an assessment of general cognitive ability, single-word reading and spelling, reading comprehension, expressive writing, and number skills (see Figure 53.3). The Wechsler scales provide tools for comprehensive assessment of these skills (*WISC-IV*; Wechsler, 2004; *WIAT-II*; Wechsler, 2005). Measures of phonological awareness, Rapid Naming and verbal short-term memory are often included because of their value as concurrent predictors of dyslexia. The assessment will have more value if it proceeds to assess the reading strategies the child is using and the nature of spelling errors, with a view to prescribing appropriate intervention and an in-depth investigation of oral language skills may be appropriate (Snowling & Stackhouse, 2006).

In the past, such assessments were the domain of educational psychologists; however, now it is often a teacher with specialist qualifications who would undertake such assessments, replacing IQ testing with assessment of language and/or nonverbal reasoning. Given the substantial overlap between reading difficulties and difficulties with mathematics, an assessment of arithmetic and mathematical reasoning using standardized tests should ideally be part of a comprehensive assessment (see Figure 53.3).

A number of different practitioners, including physiotherapists, occupational therapists, specialist teachers, and pediatricians, play a role in the assessment of DCD. It is generally agreed that such assessments should incorporate the evaluation of a range of movements as well as the impact of motor difficulties on everyday skills and psychosocial functioning. Individually administered tests of gross and fine motor

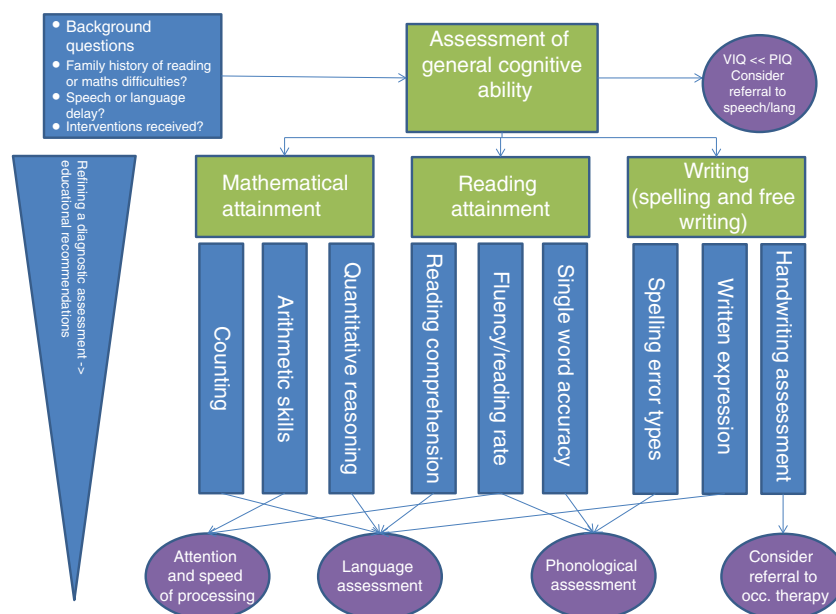

Figure 53.3 Diagram outlining the steps in a comprehensive assessment of SLD.

skills, incorporating ball skills, manipulative skills and balance are commonly used (Henderson *et al.*, 2007) and parent- and teacher-completed checklists and self-report questionnaires can be useful (Green *et al.*, 2005; Chambers & Sugden, 2006). It is also recommended that prior to an intervention program, physical fitness should be assessed.

Communicating findings

Given the dimensional nature of SLDs, it can be difficult for clinicians to provide parents with the answer to the question foremost in their mind: “Is my child dyslexic?” or perhaps “Does my child have dyscalculia?” Current practice varies considerably, and it is important for clinicians to be aware that the label dyslexia may be used differently by different agencies.

Clinicians need to provide as much feedback as possible to families, emphasizing the dimensional nature of SLDs and the comorbidities between them. The diagnostic report is critical and ideally it should outline recommendations for educational management, intervention, and advice on monitoring and review of progress.

Management of specific learning disorders

Here we will focus on principles which guide the management of dyslexia and related disorders. An extensive review of evidence on treatments for dyslexia, reading comprehension impairment, language disorders, and mathematics disorder is given in Chapter 41.

Children with speech–language difficulties are at high risk of dyslexia, especially if speech production deficits persist to school age (Bishop & Snowling, 2004). Such children should receive appropriate support during the preschool period, including speech and language therapy, and parental assistance with the development of pre-literacy skills will be helpful. However, it is important to be mindful that many children with language learning impairments may make a good start in learning to read but fail later as literacy demands increase. Careful monitoring of high-risk children is therefore advisable throughout the primary school years.

Theoretical knowledge of the relationship between phonological skills and learning to read, and phonological deficits in dyslexia has led to the development of effective reading intervention programmes that promote these skills in the context of reading (see Chapter 41). It is important to emphasize, however, that children with dyslexia can respond very slowly even to the most effective teaching approach. Because of the intractable nature of the disorder in some cases, some families turn to alternative or complementary therapies. However, for children who do not respond to conventional treatments, the best advice at the present time is to consider more intensive therapies, including placement in special units. In addition, information technologies have a lot to offer. Ideally, students

with dyslexia should be taught to become fluent keyboard users, with special instruction in the use of a spell-checker. In addition, some children with dyslexia can use voice-recognition technology as an aid to written work. In formal assessments and examinations, people with dyslexia should normally be eligible for special arrangements. The most common arrangement is extra time in written examinations. If the student has particularly poor reading and writing skills, then they may be allowed someone to read the questions to them, an amanuensis (scribe) or use of a keyboard.

In contrast to what is known about how to teach word-level reading skills, far less is known about how to promote reading comprehension effectively (Duff & Clarke, 2011; see Chapter 41). Since reading comprehension impairments stem from oral language weaknesses, the collaborative practice of speech and language therapists with teachers is likely to provide useful strategies for these children to learn.

Conclusions and future directions

Understanding of the nature and causes of children’s reading difficulties is well advanced as is knowledge about appropriate interventions. In this domain, cognitive models of reading acquisition have had a positive effect on progress. Although less is known about children’s arithmetic difficulties, the influence of cognitive models is beginning to improve methods of assessment and intervention. An advantage of the cognitive approach to SLDs is that it makes contact with what is known about typical development; furthermore, an understanding of the cognitive risk factors for disorders can foster understanding of links between genes, brain, and behavior. Future research is needed to understand the causes and treatments of motor impairments and to better understand how comorbidity changes the nature, developmental course, and outcomes of SLDs.

CHAPTER 54

Intellectual disability

Emily Simonoff

National Institute for Health Research (NIHR) Biomedical Research Centre for Mental Health, King's College London, UK

Terminology and classification

Intellectual disability (ID) refers to the presence of global and impairing deficits in intellectual functioning which commence in early life and persist with development. ID is a descriptive diagnosis with many identified causes. Over the past century, terminology has varied widely including “mental retardation” and, in the United Kingdom, both “learning disability” and “learning difficulties.” The changes reflect attempts by professionals and advocates to change social attitudes toward people with ID, who experience high levels of stigma and discrimination, and where each name has eventually become a term of abuse.

Diagnostic criteria for ID have included two mandatory elements: substantially below average intellectual function, as measured on tests of intelligence (IQ) and significant impairment in adaptive functioning. The recently published DSM-5 criteria maintain this framework, with significantly reduced IQ usually (but allowing for some variance) of two or more standard deviations below average, that is, below 70. However, the concept of functional impairment is more clearly specified. In earlier classifications, both DSM and ICD, this criterion was considered problematic to operationalize because of its vagueness and the lack of agreed measures of adaptive function. However, in recent years, several reliable and valid measures have been developed, which quantify adaptive functioning in different domains. DSM-5 places greater emphasis on the measurement of functioning in relation to communication, social skills, personal independence, and school or work functioning. As with previous classifications, there is a requirement that the impairments were evident during childhood or adolescence, explicitly excluding acquired brain injury. While the latter makes good sense with respect to etiological differences, it can become a barrier to accessing services for people with an acquired condition who are functioning in the ID range, as

services sometimes use rigid inclusion criteria, requiring an ID diagnosis.

The degree of ID is subclassified according to the extent of impairment, which should reflect a combination of IQ and level of adaptive functioning. The boundaries are not firmly fixed and serve as a guide. Mild ID is associated with IQ of 50–69, moderate 35–49, severe ID 20–35, and profound ID below 20. In contrast to clinicians, researchers often distinguish only two groups, referred to as mild (IQ 50–69) and severe ID (IQ below 50), discussed below under the two-group theory.

While adaptive function correlates moderately well with IQ at a group level (Papazoglou *et al.*, 2013), there are considerable individual differences. In general, people with autism spectrum disorders (ASDs) perform more poorly on measures of adaptive functioning than would be expected on the basis of their IQ (Charman *et al.*, 2011). Genetic syndromes show different relationships between IQ and adaptive function, both cross-sectionally and over time. For example, children with both Fragile X and Williams Syndrome have greater discrepancies between IQ and adaptive function than those with neurofibromatosis type 1 (NF1) and the former two also show age-related relative decline in adaptive function while NF1 does not (Fisch *et al.*, 2007). Individual circumstances may also influence the level of adaptive function with family stress and adversity associated with poorer functioning (Koskentausta *et al.*, 2007) and engagement in daily living activities appropriate for developmental level associated with enhanced functioning (Felce & Emerson, 2001).

From a clinical perspective, the requirement for impairment in adaptive function in ID is consistent with diagnostic criteria for other mental disorders which also require impact on functioning. However, from a research perspective, the coupling of the two criteria limits the ability of researchers to explore the factors associated with variation in adaptive behavior in people of subaverage IQ. Until recently, there has also been a paucity of

brief measures suitable for use in research studies and these have often defined the population of study on the basis of IQ alone.

Epidemiology of intellectual disability

Level of IQ is a key criterion in defining ID; because IQ tests are designed to be normally distributed with a mean of 100 and standard deviation of 15, on this basis alone, 2.3% of the population would be expected to have IQ <70. In fact, one recent meta-analysis showed that studies report prevalence rates ranging from 3.31 to 156.03/1000 population (Maulik *et al.*, 2011). While variation across populations is expected, the wide range cannot be accurate and is almost certainly due to methodological flaws. IQ is a truly continuously distributed trait and any threshold will be arbitrary; there are no “gold standards” or biomarkers for ID. Therefore, operational definitions that combine IQ with impairment in adaptive function and produce a prevalence rate in Western countries that is in the region of 2–3% are the best practical solution at present, although scientifically unsatisfactory. However, a number of factors are known to influence reported prevalence. The first is mode of *ascertainment*, where there are large and consistent differences in reported prevalence rates according to whether ascertainment is via whole population screening, leading to higher rates, or by the use of registers of preidentified cases. There is less variation for severe ID (IQ <50) and an earlier summary reported rates ranging from 3 to 7/1000 while comparable rates for mild ID (IQ 50–69) ranged from 5 to 80/1000 (Roeleveld *et al.*, 1997). This reflects the fact that people with severe ID are more likely to be included in administrative registers and that mode of ascertainment is less crucial for this group.

Second, studies using IQ as the sole criterion report higher rates than those also including adaptive function (Maulik *et al.*, 2011). Studies employing more systematic ascertainment strategies are also more likely to base their definition on cognitive criteria alone and these effects are difficult to disentangle. Third, studies of children and adolescents report substantially higher rates than those of adults. This finding is confounded with both mode of ascertainment and method of assessment, but other factors such as selective mortality may play a role. When applying definitions that include adaptive function, it is possible that people with milder cognitive impairments are most adversely affected during their education and that appropriate adult employment lessens the impact on functioning. Milder levels of ID may not be recognized, however, before school-age, and cognitive testing in children under 6 years is unreliable (Anastasi & Urbina, 1997).

Fourth, higher rates of ID are also found in low- and medium-compared with high-income countries, with a meta-analysis reporting comparative rates of 16.41, 15.94, and 9.21/1000, for low- medium- and high-income countries respectively (Maulik *et al.*, 2011). Many of the studies undertaken in low-income countries have significant methodological flaws, including

the use of nonstandardized and nonspecific assessments that may identify other types of disability. This raises the issue of “culture-fair” tests of intelligence, which aim to be less reliant on prior experience and learning. Cognitive assessments not only need to be standardized for the population in which they are used but also need to take into consideration the cognitive characteristics that are associated with successful independent functioning. In the past, it has been argued strongly that people living in agrarian and rural societies, exposed to different educational practices, need different cognitive skills than those living in high-income, industrialized societies. With increasing globalization, there will be greater consistency in the cognitive skills associated with good adult functioning. However, variation in exposure to formal education, as opposed to underlying ability, remains an important factor influencing performance on cognitive tests. Despite the limitations in interpretation imposed by methodological considerations, rates of ID are greater in more impoverished countries.

Factors influencing the prevalence of intellectual disability

Severity

As highlighted above, mild ID is more common than severe (IQ <50) forms of the disorder, with the former accounting for about 85% of all ID. This is predicted from the normal distribution of the IQ scores. However, rates of severe ID may be greater than would be expected, because of an increase in pathological causes of ID. In some respects, this is a tautological question, as the test standardization is based on the distribution of test scores. Furthermore, IQ scores at the extreme lower end are not precise and many standard tests do not provide scores below IQ of 40.

Sex

The available studies are consistent in finding about a 20% male excess for severe ID (Roeleveld *et al.*, 1997). Reasons include the role of X-linked genetic disorders, including fragile X and many other, less common disorders. Greater male vulnerability to adverse environmental experiences is also cited. In mild ID, the aggregate data also suggest a male excess, but the ratio varies considerably across studies and those with more complete ascertainment are less likely to demonstrate a male preponderance (Roeleveld *et al.*, 1997; Simonoff *et al.*, 2006).

Socioeconomic factors

Various indices of socioeconomic adversity in developed countries are associated with mild ID (Drews *et al.*, 1995; Leonard and Wen 2002; Emerson *et al.*, 2006) but less so or not at all with severe ID (Broman *et al.*, 1987; Roeleveld *et al.*, 1997). Studies in developing countries have identified a relationship to both mild and severe ID (Gustavson, 2005) which is at least partly due to increased exposure to risk factors such as obstetric adversity, environmental toxins, and poor schooling (Brooks-Gunn & Duncan, 1997). In high-income countries, raising a child with

ID is associated with significant direct and opportunity costs, as demonstrated for autism (Knapp *et al.*, 2009). What is less clear is whether genetic risk factors are also at play. Hence, parental socioeconomic disadvantage may also index intellectual impairment in parents, which increases the risk of ID in their offspring. However, even if this were the case, the effects of poverty on children are themselves undesirable.

Ethnicity

Attempts to disentangle ethnicity from related risk factors for ID have proved highly controversial. Studies in the United States (Croen *et al.*, 2001) and Australia (Australian Institute of Health and Welfare & O'Rance, 2007) show that ethnic minorities are more likely to be affected, and the relationship is largely with mild ID. However, when prevalence rates are adjusted for indices of social disadvantage, maternal education, maternal age, birth order, and economic status, the risk associated with minority status is reduced or eliminated (Yeargin-Allsopp *et al.*, 1995). Ethnic groups vary in their genetic makeup, and this could contribute to differences in prevalence rates, although the variation is likely to be small. Furthermore, studies from different countries report higher rates in minority and/or socially deprived groups, whatever the ethnic origin, suggesting that a particular ethnic makeup is not a primary explanation. However, consanguinity, which occurs more commonly in certain ethnic groups, is a cause of recessive genetic disorders that are associated with ID.

Higher rates in low- and middle-income countries

A multitude of factors are likely responsible for higher rates in low and middle income countries. The lack of available antenatal screening increases the burden of genetic disorders and poor antenatal care contributes to high rates of obstetric complications, with one study suggesting that more than half the cases of ID were potentially preventable through improvement in these two elements alone (Dave *et al.*, 2005). Poor nutrition, exposure to environmental toxins, and pre- and postnatal infections also play a significant role.

Causes of intellectual disability

The two-group theory of ID was first proposed by Lewis (1933) and Penrose (1938, 1939) and subsequently elaborated by Zigler and colleagues (Zigler, 1967). It distinguishes between "pathological" and "sociocultural/familial" mechanisms as discrete causes of ID, and links these to severe versus mild ID. Pathological causes included relatively rare medical-genetic and extreme environmental events that almost invariably lead to ID. In contrast, the sociocultural/familial form of ID was postulated to be caused by common adverse family- and socially based risk factors, including low parental IQ, lack of environmental stimulation, and social deprivation. Pathological causes were also thought to cause severe ID (IQ <50), while sociocultural/familial factors were associated with mild ID and

borderline intelligence. It is helpful clinically to differentiate individuals based on the severity of intellectual impairment, in determining investigations, planning interventions, and guiding longer-term prognosis. However, the dichotomy is overrestrictive in applying a threshold to a truly continuous trait. This is especially the case in terms of causation. People with genetic disorders, such as Down syndrome and Fragile X, vary in IQ from average ability to severe impairment, and the same applies for those experiencing severe environmental adversity such as prematurity. Similarly, families with high rates of ID and socioenvironmental adversity may have members with severe as well as mild ID (Broman *et al.*, 1987). However, despite the limitations of the two-group theory, causes and severity of ID are linked and it is often helpful to consider different etiologies in the context of the degree of intellectual impairment, as well as other factors such as associated physical, cognitive, and behavioral features.

Genetic factors

Twin and adoption studies consistently indicate that intelligence in the general population is moderately heritable (Calvin *et al.*, 2012; Nisbett *et al.*, 2012; see Chapter 24). Several twin studies have examined intelligence at the extreme low end of the general population, including mild ID. Two of these report heritabilities that are similar to those seen in the rest of the IQ range (Cherny *et al.*, 1992; Thompson *et al.*, 1993), while the third, conducted in preschool children, suggests a somewhat higher heritability in the low end of the distribution (Spinath *et al.*, 2004). These findings suggest that inherited genetic factors are at least as important in determining intelligence in people with borderline intelligence and mild ID as in the rest of the population, although of course the level of intelligence is different.

Two large family studies of ID suggested that mild, but not severe, ID aggregates in families of affected individuals (Reed, 1965; Nichols & Broman, 1974). However, a further study of mild ID indicated that recurrence risk depended on whether other family members were affected, increasing the recurrence rate to ~35% (Bundey *et al.*, 1989). Recent research has focussed on identifying individual genetic risk factors and their mechanisms.

Chromosomal anomalies are variations from the usual diploid set of chromosomes or segments of chromosomes. They are typically identified by cytogenetic analysis, which can identify abnormalities in chromosomal segments down to a resolution of 5–10 mega bases (mB). Chromosomal anomalies identified with cytogenetic methods account for ~15% of severe ID (Ropers, 2010). Down syndrome (trisomy 21) is the most common chromosomal anomaly causing ID, occurring in about 1.5 per 1000 pregnancies (Siffel *et al.*, 2004). Like other chromosomal anomalies, Down syndrome is significantly associated with advanced maternal age, with a 6.5-fold increase in incidence among women over 35 years (Siffel *et al.*, 2004).

Sex chromosome anomalies are the most common group of chromosomal anomalies in live-born infants. The most frequent

are Klinefelter syndrome (XXY), Turner syndrome (XO) and XYY syndrome. Aggregate prevalence is about 2–5 per 1000 with Klinefelter syndrome the most common (Maeda *et al.*, 1991). Most people with sex chromosomal anomalies have IQs that are in the low normal/borderline range but occasionally mild ID. Speech/language problems are common as are social and behavioral difficulties (Leggett *et al.*, 2010).

Mutations in all forms of Mendelian inheritance are causes of ID. Common *autosomal dominant* disorders include NF1, Noonan syndrome, and tuberous sclerosis. Autosomal dominant disorders are characteristically passed from one generation to the next; therefore these causes are typically characterized either by high rates of new mutations, for example, tuberous sclerosis, or a highly variable phenotype, for example, neurofibromatosis. In addition to these well-recognized disorders, new genetic methods such as mutation screening targeted at genes known to be involved in cognitive function, have provided the technological basis to identify novel heterozygous (and therefore presumably dominant) genetic mutations associated with nonsyndromic ID (Ropers, 2010).

Autosomal recessive causes of ID are often associated with more severe forms of ID; those that were first recognized often involved inborn errors of metabolism, such as phenylketonuria or homocystinuria, identified through biochemical investigations. Recently, the use of single nucleotide polymorphism (SNP)-based arrays has identified regions of homozygosity. This technique has been used to study families with nonsyndromic autosomal recessive ID, including those with consanguinity, and has led to the identification of a number of new causative mutations (Ropers, 2010).

Current estimates suggest that *X-linked* genetic disorders account for 10–12% of all ID in males; at least, 91 X-linked genes have been identified (Ropers, 2008). Fragile X syndrome is the most common cause of X-linked ID, but its pattern of inheritance is complex, involving intergenerational expansion in the FMR1 gene causing the mutation, so that familial inheritance is not typical of X-linked inheritance (Loesch & Hagerman, 2012). Fragile X occurs in about one in 5000 males and females can also be affected (Coffee *et al.*, 2009). Individuals with a repeated sequence of DNA (three nucleotides, called trinucleotide repeats) in the “premutation” range may present with a milder condition that includes premature ovarian failure, a neurodegenerative disorder in older adults, and fragile X-associated tremor/ataxia (Hagerman *et al.*, 2004). Other forms of X-linked ID are very heterogeneous and are therefore broadly classified into the syndromic forms, in which there is a recognizable and fairly consistent physical and behavioral phenotype, and the nonsyndromic forms, which are more variable and may not include features beyond ID (Chiurazzi *et al.*, 2008; Ropers, 2008).

Advances in molecular genetic methods have identified much smaller duplications and deletions of chromosomal regions, well below the resolution of light microscopy. Using these techniques, the underlying “*microdeletion*” was identified for

Williams (deletion of 7q11.23) and Smith-Magenis syndromes (deletion of 17p12) (Mefford *et al.*, 2012). Subsequently, much smaller deletions and duplications, referred to as copy number variants (CNVs), have been identified in ID. With the current molecular genetic techniques, CNVs are thought to be causal in about 15% of children presenting with developmental delay and it is now proving useful to review patients with previously idiopathic ID, as genetic abnormalities are now revealed in a substantial minority (Mefford *et al.*, 2012). However, some CNVs will represent normal variation rather than a pathogenic mutation and this proportion will only increase as the techniques detect smaller variations. CNVs are more likely to be pathogenic when larger in size, when replicated across unrelated individuals with ID/developmental disorder, and when they occur *de novo* in a child whose parents are unaffected with ID. Craniofacial dysmorphisms often characterize the population in whom CNVs are identified (Ropers, 2010).

Imprinted disorders are ones in which the parental origin of the genetic abnormality alters the phenotype. Prader–Willi and Angelman syndromes are both due to abnormalities in the chromosomal region 15q11–13 but with very different phenotypes. The absence of a paternally derived copy of this region, whether through deletion or uniparental disomy, causes Prader–Willi syndrome, typically with mild ID. In contrast, Angelman syndrome, with severe to profound ID, is caused by deletion of the maternal region or a mutation in the UBE3A gene. Finally, a maternal duplication in this region is reported in 1–3% of patients with autism (Hogart *et al.*, 2010).

Other medical disorders associated with ID

A host of disorders that affect brain structure or function are associated with ID (see Chapter 31). Epilepsy is more common in people with ID and is related to its severity, occurring in about 7% of children with mild ID versus 35% with severe ID (Airaksinen *et al.*, 2000). Cerebral palsy and meningo-encephalitis are other medical causes. By definition, ID is diagnosed when impairment in cognitive function occurs during the “developmental period,” leaving some ambiguity about the diagnostic classification of low IQ among those with early exposure to insults such as acquired brain injuries and exposures to toxins. However, these are important conditions to note from a public health perspective as they represent tractable targets in reducing low IQ.

Environmental factors

There is wide variation across countries in which environmental risks are most common. Premature birth and the impact of hypoxia continue to be a risk factor in all societies. In those with good neonatal care, cognitive outcomes are generally good for those born at 32 weeks gestation or later, while those who were very preterm or of very low birth weight are at increased risk of low IQ and ID (Marlow, 2004; Aylward, 2005). In low- and middle-income countries, obstetric complications currently

account for about 10% of severe ID (Lundvall *et al.*, 2012). The care of high-risk neonates is constantly improving and outcome studies are by definition out of date, but in general as survival and major morbidity have improved, more subtle developmental problems have become more obvious. These include not only ID but also educational difficulties often related to specific cognitive impairments (Hutchinson *et al.*, 2013). The role of milder “obstetric suboptimality” as a causal risk factor is less clear; the observation that infants with Down and Prader–Willi syndromes have increased rates of obstetric complications highlights the role of fetal characteristics in the pregnancy. Obstetric problems are also seen when there has been poor antenatal care, which may arise from factors associated with immigrant status, social deprivation, and maternal ID/mental disorder.

Certain maternal infections during pregnancy, including toxoplasmosis, cytomegalovirus, rubella, and herpes, are well-recognized causes of infant morbidities, which include ID. Prenatal exposure to toxins is an important and potentially preventable risk. In societies where alcohol is freely available, this is the leading toxin cause of ID; fetal alcohol syndrome (FAS) occurs in 0.5–3 per 1000 births (May & Gossage, 2001) and accounts for as much as 3% of ID (O’Leary *et al.*, 2013). However, rates of FAS and FAS spectrum disorder also vary widely and diagnostic practice is a key factor. Rates are lower when the dual criteria of physical stigmata, such as the classical facies, and a history of heavy prenatal alcohol use are applied, than when only a history of heavy alcohol use in pregnancy is applied. The physical features are variable and sometimes subtle; it is likely that there is underdiagnosis under the former practice and overdiagnosis in the latter. Congenital hypothyroidism is detected with routine screening in one in 3000 pregnancies in high-income countries and is associated with both low IQ and ID (Grosse *et al.*, 2011). Newborn screening is important but suffers from false positive results (Buyukgebiz, 2006). Exposure to heavy metals such as arsenic and mercury during pregnancy and/or infancy is also associated with ID (McDermott *et al.*, 2012) while childhood lead exposure is a risk factor for low IQ and ID (Needleman *et al.*, 1990; Nevin, 2009). All these risk factors are considerably increased in low-income countries and will contribute to the increased rate of ID.

As described above, socioeconomic adversity is associated with increased rates of ID, but the mechanisms are complex and bidirectional. Severe and chronic social deprivation is a direct cause, as exemplified by the poor early institutional rearing experienced by the English Romanian adoptees (Rutter *et al.*, 2004). Grantham-McGregor and colleagues demonstrated the beneficial medium- and long-term effects of early childhood psychosocial stimulation on growth-retarded infants and children from several low-income countries, including Jamaica and Bangladesh (Gardner *et al.*, 2005; Walker *et al.*, 2006; Walker *et al.*, 2010). Interestingly, psychosocial stimulation was more effective than nutritional supplementation in improving both cognition and behavior (Gardner *et al.*, 2005; Walker *et al.*, 2006).

Biology-environmental interplay

As with other behavioral and cognitive phenotypes, many risk factors for ID increase susceptibility but are not deterministic. Hence, genetic mutations that are risk factors for ID can be inherited as well as occurring *de novo* in a child with ID. Zinc supplementation for malnourished children was most effective in improving cognition and coordination when administered alongside psychosocial stimulation (Gardner *et al.*, 2005). Similarly, the effects of prenatal alcohol exposure are not invariant, as demonstrated by a small (and statistically nonsignificant) twin study showing concordance for FAS among all five pairs of MZ but only seven of 11 DZ twin pairs (Streissguth & Dehaene, 1993). The same applies to preterm birth, where there is wide variability in cognitive outcomes (Moore *et al.*, 2012). The IQ of boys with Fragile X syndrome is significantly influenced by the quality of their home environment (Dyer-Friedman *et al.*, 2002). Clearly, a better understanding of the environmental mediators and moderators of biological risk has the potential to improve interventions for high-risk groups.

Assessment and diagnosis of intellectual disability

Early identification of ID provides the possibility for children to receive appropriate support from education, health, and social services. Parents often find a diagnosis aids their understanding of their child, especially if strengths as well as impairments are identified. Furthermore, if a genetic cause for ID is identified, it may influence family planning. In general, severe ID is identified early in life, while mild ID may not be recognized, particularly in the absence of additional medical problems. Therefore, clinicians should be alert to more subtle indicators, such as school nonattendance, poor academic performance, and immaturity of interests and behavior. School reports with information about attainments as well as behavior can be helpful. A common clinical error is to misattribute these warning signs to other factors, such as adverse early experiences, family stress, or other risk factors, and to fail to consider ID.

History

The history should consider intellectual development, to establish that the present level of functioning is consistent with that at an earlier age and that there is no history of regression. The gap between the achievements of a child with average intelligence and one with ID becomes more obvious with age, and parents of children with mild ID are often only aware of differences when their child starts school. Loss of skills or stasis in development during the first 3 years is common in autism, and indeed almost pathognomonic (Pickles *et al.*, 2009). However, a clear history of loss of skills after the age of 3 years should trigger referral to a pediatric neurologist for further investigation.

The history should also elicit any risk factors for ID, genetic, other medical, or environmental. A three-generation family

history, including ID, and neurological and specific developmental disorders, should be obtained. ID may not have been formally diagnosed in relatives and questions should include difficulties with routine scholastic attainments and extra support required at school. The obstetric history should include prescribed and recreational drugs, alcohol and tobacco use, physical trauma, as well as any other indicators of suboptimality. A full medical history for the child should identify any neurological, neuromuscular or brain-based conditions such as epilepsy, cerebral palsy, or muscular dystrophy. General health problems are both more common in people with ID and also more likely to be overlooked (Allerton *et al.*, 2011). Enquiry should establish that hearing and vision have been assessed.

Educational history should identify the type of school attended and any additional academic and pastoral support received. Liaison with schools will ensure that academic and social support and expectations are appropriate. For older adolescents, plans for extended education and training (post statutory leaving age) should be identified.

Psychological assessment

In making the diagnosis of ID, a careful cognitive assessment is required. In the busy clinic, a pragmatic alternative may be to first undertake brief cognitive screening administered by a wide range of professionals. Care should be taken to ensure assessment is valid; with more behaviorally disturbed children, flexibility in approach is important. However, only a very small proportion of children are truly “untestable.” Even when the diagnosis of ID is clear from the history and observation, a cognitive assessment at some stage is recommended because establishing cognitive level and strengths within the profile is often important in planning educational strategies and behavioral management.

The diagnosis of ID should only be given once low IQ and impairment in adaptive function are both established. The latter is often evident from the history and presentation. In other cases where it is less apparent, a structured review should focus on everyday functioning in the domains of communication, conceptual understanding, motor skills, self-care, and independence. Several standardized measures will quantify these characteristics (Sparrow *et al.*, 1984; Harrison & Oakland, 2003).

Physical examination and investigations

The role of the child psychiatrist in undertaking a physical examination and organizing appropriate investigations varies across health care systems. Regardless of local arrangements, child and adolescent mental health services may be the first to identify the presence of ID and will have responsibility for arranging for examination and investigations. A comprehensive physical examination is required, both to look for stigmata of underlying cause of ID and also to identify co-occurring health problems. Screening for impairments in hearing and vision should be undertaken in early childhood and repeated if there is suspicion of a problem. The presence of several dysmorphic

features, particularly craniofacial dysmorphisms, are suggestive of an underlying genetic etiology (Caliskan *et al.*, 2005; Toriello, 2008). Common skin abnormalities of note include café au lait spots in neurofibromatosis and areas of depigmentation, detected by Wood's lamp, in tuberous sclerosis. Delayed motor coordination with some degree of clumsiness is common and may represent a nonspecific developmental immaturity. However, focal neurological signs suggest an additional condition that warrants further investigation. The diagnosis of epilepsy should be made by a specialist, on clinical grounds rather than on the basis of the electroencephalogram (EEG), which frequently reveals nonspecific abnormalities in people with ID (National Institute for Health and Care Excellence, 2012).

There is increasing consensus that genetic testing should be undertaken routinely in people with ID (Morrow, 2010; Ropers, 2010; Mefford *et al.*, 2012). The technology employed for such assessments is changing on an almost annual basis. Hence, at the time of writing, the favored technique is array comparative genome hybridization (array CGH), which picks up major chromosomal abnormalities as well as many CNVs. However, this is likely in the near future to be superseded by more sensitive measures. Genetic testing should be performed in conjunction with the regional specialist genetics center, to ensure the appropriate investigations and interpretation of any findings (see Chapter 24). Furthermore, the utility of retesting people in whom genetic tests were previously negative should be reviewed with specialist colleagues (Baker *et al.*, 2012b; Rauch *et al.*, 2012). Positive findings from genetic testing may not only identify risks for other family members but may also highlight associated features of a genetic syndrome where early intervention may be helpful, such as the more subtle cardiac problems in Noonan syndrome and 22q deletion syndrome.

Other universally agreed investigations, where no cause of ID has been established, include a full blood count, urea and electrolytes, creatine kinases, lead, thyroid function, urate, ferritin, and biotinidase (McDonald *et al.*, 2006). Recommendations regarding other investigations are less consistent. The rate of diagnostically meaningful findings from routine MRI scanning is 1% or less (McDonald *et al.*, 2006); it is recommended as a routine investigation in the United States (Michelson *et al.*, 2011) but not the United Kingdom (McDonald *et al.*, 2006). Routine metabolic screening is not recommended but should be considered in selected groups, including those from highly inbred populations or where there is parental consanguinity, an affected sibling, episodic de-compensation, suggestive dysmorphic features, ophthalmic abnormalities, and failure of growth (Shevell, 2008).

Longitudinal course of intellectual disability

Although ID typically involves a life-persistent diminution in cognitive function, there is considerable variability in the course and adaptive outcomes of individuals. Children who have

experienced significant environmental deprivation may show substantial intellectual gains with appropriate environmental stimulation, including placement in typical families (Beckett *et al.*, 2006; Walker *et al.*, 2010). Across the population, while the broad aspects of a child's intellectual ability may be apparent in early childhood, prediction of later IQ from tests performed under the age of 6 years is poor (Anastasi & Urbina, 1997) and it is often best to wait until the child is in mid- to late-childhood to discuss long-term plans with parents and carers.

Over and above the age-related widening gap in cognition and skills, several disorders, including Down syndrome, fragile X and Williams syndrome, show a relative decline in IQ from childhood through adolescence and early adult life, including Alzheimer dementia in Down syndrome (Fisch *et al.*, 2007). NF1 is different, with cognitive skills continuing along the same trajectory. In contrast, one longitudinal assessment showed that adolescents with either autism or with Down syndrome continued to acquire new functional skills into the mid-20s (Hastings & Beck, 2004; Smith *et al.*, 2012a). Several tentative lessons emerge. First, the developmental pattern of cognitive ability may be disorder-specific. Second, daily living skills can continue to develop into adult life among those with ID. Third, trajectories for cognition and daily living skills may not run in parallel, and divergence may depend on the individual disorder.

Mortality is increased among those with severe to profound ID, with an overall excess of 2.5- to 3-fold (Tyrer & McGrother, 2009) and most common in early adulthood (Tyrer *et al.*, 2007). Central nervous system disorders, congenital anomalies, and mental disorders including dementia are particular risk factors, but most causes are increased in people with ID.

Behavioral phenotypes

The term “behavioral phenotype” refers to a relatively predictable set of behavioral and sometimes cognitive characteristics that occur in individuals with a known genetic abnormality (see Chapter 31). The individual features of behavioral phenotypes may be common or rare; what distinguishes these conditions is the typical *combination* of features and their association with a particular condition. This is useful for clinicians in predicting behaviors and preventing negative consequences, such as compulsive overeating with severe obesity in Prader-Willi syndrome. From the other direction, observing a characteristic pattern of behaviors may provoke specific genetic testing, leading to a diagnosis that is relevant to other family members. It should be noted that no behavioral phenotype is invariant; for example, schizophreniform psychosis occurs in only ~25% of people with 22q deletion syndrome (formerly referred to as velocardiofacial syndrome) (Murphy, 2005); however, no other single risk factor is so strongly associated with psychosis. Researchers are particularly interested in behavioral phenotypes because of the light they can shed on the biological pathways involved in gene-cognition-behavior links. Table 54.1

describes the most well-known behavioral phenotypes and their underlying etiology.

Mental disorders in children and adolescents with intellectual disability

Prevalence rates for psychiatric disorders in children and adolescents with ID are consistently increased 3- to 5-fold (Einfeld *et al.*, 2011). The entire range of psychiatric disorders is increased in ID (Dekker *et al.*, 2002; Emerson, 2003). However, the two greatest increases occur for children with ASD, of whom about 50% have ID (Charman *et al.*, 2011) and for attention deficit hyperactivity disorder (ADHD) where 15–20% have ID (Emerson, 2003; Simonoff *et al.*, 2007). Emotional and behavioral problems are roughly equally increased (about threefold) according to parent reports, but teacher ratings detect fewer emotional (about twofold increase) than behavioral problems (about threefold increase) (Dekker *et al.*, 2002; Emerson, 2003; Simonoff *et al.*, 2007).

Differences in psychiatric presentation among children with ID

As the degree of intellectual impairment increases, the risk for both ASD and ADHD increases (Gillberg *et al.*, 1986; Simonoff *et al.*, 2007). At the same time, differentiating specific psychiatric disorders becomes more difficult (Gillberg *et al.*, 1986) and eliciting a history and/or mental state that fulfills diagnostic criteria can be problematic. First, it may be difficult to identify symptoms that require the behavior to be inappropriate for developmental age, such as ASD or ADHD, in those with severe or profound ID. Second, the mental state is more difficult to examine in people with severe communication impairments, and informants may have limited insight into internal experiences. Third, some disorders include symptoms that require higher cognitive processes, such as hopelessness and helplessness in depression. For all these reasons, there has been a movement for a separate psychiatric classification with modified criteria for people with severe to profound ID and at least one system has been proposed for adults (Royal College of Psychiatrists, 2001).

The syndrome of “behavior that challenges”: a distinct condition?

Although alternative classification systems have not gained widespread acceptance, terms such as “behavior that challenges” or “maladaptive behavior” are frequently used to describe a syndrome of problematic behavior that is relatively specific to people with ID and associated neurodevelopmental disorders such as ASD. Behavior that challenges refers to aggression directed at others or self, severe temper tantrums, destruction of property, and high levels of noncompliance. The lack of consensus regarding operational criteria hinders prevalence estimates, but most population-based studies report rates of ~10% in

Table 54.1 Behavioral phenotypes.

Name of condition	Genetic abnormality	Behavioral/cognitive features	Physical and other features
Down syndrome (Trisomy 21)	Additional chromosome 21 (95% of cases) or chromosomal translocation causing partial trisomy (~4%) or chromosomal mosaicism (~1%)	Wide IQ variation from low average to severe ID, mainly mild to moderate ID. Wide variety of behavior (in contrast to previous view of very sociable personality) Relative strength in social communication. Alzheimer disease in mid-to-late adulthood. Epilepsy in 5–10%	Classical dysmorphic features include epicanthal folds, upward-slanting palpebral fissures, Brushfield spots, and palmar crease Wide and variable range including cardiac and gastrointestinal congenital anomalies, hearing loss secondary to impaired nasopharyngeal structures Mild growth retardation. Increased rates of leukemia, hypothyroidism and altered immune function
Rett syndrome	X-linked mutation in MECP2 gene, affecting girls only as lethal in males	Normal early development with abnormalities beginning toward end of first year; some autistic symptoms, compulsive hand movements, hyperventilation. Often stabilizes in mid-to-late childhood with no further progression, bruxisms Profound ID	Deceleration of head growth leading to microcephaly, short stature. Constipation and gastro-oesophageal reflux, prolonged QT interval on ECG, spasticity, seizures, ataxia
Lesch–Nyhan syndrome	X-linked mutation in hypoxanthine–guanine phosphoribosyltransferase gene	Low average to mild ID is typical, severe self-injurious behavior, typically compulsive biting of fingers and lips	Spastic cerebral palsy, choereothetosis, uric acid urinary stones
Cornelia de Lange syndrome	Marked genetic heterogeneity: 50% of cases with mutation in NIPBL gene but also cases with mutations in X-linked SMC1A gene, SMC3, CDLS4, RAD21, and HDAC8 (also X-linked). All involved in two systems pathways	Typically severe ID but variable IQ into normal range Self-injurious behavior Communication relatively impaired compared to adaptive function	Multiple and variable abnormalities but typical facial features include low anterior hairline, arched eyebrows, anteverted nares, maxillary prognathism, long philtrum, thin lips, and “carp” mouth Prenatal and postnatal growth retardation Ptosis, nystagmus and high myopia Microcephaly Gastro-oesophageal reflux in ~60%, hypothesized to be a cause of behavior that challenges Notable features include long face, large ears, and prominent jaw and macroorchidism, typically postpubertally
Fragile X Syndrome	X-linked expanding trinucleotide repeat in FMR1 gene, affecting males more commonly but also females Fragile X tremor/ataxia syndrome caused by smaller size of expanded trinucleotide repeat	Variable level of ID, typically moderate to severe but including mild and borderline Variable behavioral manifestations include hyperactivity and ADHD, poor eye contact and autistic features	

Table 54.1 (continued)

Name of condition	Genetic abnormality	Behavioral/cognitive features	Physical and other features
Prader–Willi Syndrome	<p>Caused by deletion or disruption of a gene or several genes on paternal chromosome 15 or maternal uniparental of same region.</p> <p>Overlapping clinical phenotype in chromosome 15q11–q13 duplication syndrome</p>	<p>Mild ID/borderline IQ. Excessive appetite in which food-seeking behavior can cause behavior that challenges. Excessive daytime sleepiness with sleep architecture abnormalities. Delayed motor milestones and speech difficulties. Skin-picking</p>	<p>Features include diminished fetal activity, neonatal hypotonia, subsequent obesity, muscular hypotonia, short stature, hypogonadotropic hypogonadism, and small hands and feet</p> <p>Depigmentation compared to family members</p>
Angelman syndrome	<p>~70% maternal deletions involving chromosome 15q11.2–q13 (same region as Prader–Willi); ~2% paternal uniparental disomy, 2–3% result from imprinting defects. Some of the remaining due to UBE3A gene mutations. protein ligase E3A gene (UBE3A; mutations in the MECP2 gene can present a similar phenotype)</p>	<p>Usually severe to profound ID with absence of speech, episodic paroxysmal laughter</p>	<p>Features include ataxia, hypotonia, epilepsy, unusual large mandible and open-mouthed expression revealing the tongue</p> <p>Frequent depigmentation relative to family members</p>
22q deletion syndrome (previously Velocardiofacial Syndrome)	<p>Deletion involving chromosome 22q11</p>	<p>Mild ID to borderline IQ is typical</p> <p>Childhood features include ADHD, autistic features. Mood swings are also common</p> <p>In adolescence/adulthood, ~25% develop schizophreniform psychosis</p>	<p>Highly variable but main features include cleft palate and cardiac anomalies. Typical facies involve marrow palpebral fissures, square nasal root. Less frequent features include microcephaly, short stature, slender hands and digits, minor auricular anomalies, and inguinal hernia</p>
Smith–Magenis Syndrome	<p>Deletion in chromosome 17p11</p>	<p>Severe ID is usual, often with additional speech delay. Typically includes severe self-injurious behavior, disruptive/aggressive outbursts, sleep disturbance, possibly with absence of REM sleep, hyperactivity, and ADHD may occur</p>	<p>Common features include broad flat face, brachycephaly, midface hypoplasia, prognathism, hoarse voice, and peripheral neuropathy</p>
Williams syndrome	<p>Deletion in chromosome 7q11.</p>	<p>Moderate ID to borderline IQ. Language acquisition delayed but subsequent superficially good expressive language with high sociability but a failure of social flexibility. Often anxious despite friendliness</p>	<p>Supravalvular aortic stenosis is common. Distinctive facies involve broad forehead, medial eyebrow flare, periorbital fullness, strabismus, stellate iris pattern, flat nasal bridge, malar flattening, full cheeks and lips, long smooth philtrum, pointed chin, wide mouth and dental deformities. Infantile hypercalcaemia is frequent as is a harsh, brassy voice</p>

people with ID (Emerson *et al.*, 2001; McClintock *et al.*, 2003). It is not associated with other features of oppositional defiant or conduct disorder, such as spiteful or vindictive behavior, stealing or truanting. Furthermore, unlike oppositional defiant or conduct disorder, it does not appear to be associated with family adversity and rather shows person-specific correlates, including male sex, lower adaptive functioning, poor communication skills, a diagnosis of ASD and physical conditions causing pain (Emerson *et al.*, 2001; McClintock *et al.*, 2003). Furthermore, self-injury occurring in the context of behavior that challenges typically lacks the intentions associated with suicidal behavior or deliberate self-harm and often includes stereotypies, for example, head-banging, and/or sensory, for example, picking or biting elements.

Clinicians find the term useful because it highlights the need for different types of assessment and interventions. Applied behavior analysis (ABA) conceptualizes behavior that challenges in relation to learning theory, with maladaptive behaviors arising for a host of reasons but being reinforced, often inadvertently. While this is an important viewpoint, others are equally important. Certain genetic conditions, such as Prader–Willi and Cornelia de Lange syndromes, are particularly prone to show such behavior and the pattern of aggression/self-injury may vary, highlighting the role of biological factors (Petty & Oliver, 2005; Arron *et al.*, 2011). Recent research has expanded the causes of behavior that challenges to implicate a wide range of psychiatric disorders such as ADHD, anxiety, depression, and psychosis (Moss *et al.*, 2000; Tsiouris *et al.*, 2011), subdiagnostic traits such as low mood (Hayes *et al.*, 2011), poor impulse control (Burbidge *et al.*, 2010), and repetitive/stereotyped behaviors (Oliver *et al.*, 2012). Any condition causing pain or discomfort may cause behavior that challenges, including chronic physical disorders, acute infection or inflammation, and adverse effects of treatments (McGuire *et al.*, 2010; Oliver & Richards, 2010).

Risk factors for psychiatric disorders in ID

Several mechanisms are involved in explaining the increased risk for psychiatric disorders in children with ID. First, a number of risk factors are *shared* between ID and psychiatric disorder, contributing to their co-occurrence. *Genetic* risk factors have been linked to autism, ADHD, and ID. Twin studies of general population samples report moderate genetic correlations between lower IQ and ADHD (Kuntsi *et al.*, 2004) and somewhat smaller between low IQ and ASD traits (Hoekstra *et al.*, 2009). Molecular genetic studies have identified the same CNVs in samples selected for ADHD, ASD, and/or ID (Morrow, 2010; Williams *et al.*, 2010; Mefford *et al.*, 2012). A host of *medical* adversities, such as epilepsy, cerebral palsy, and acquired brain injury, that affect brain structure and/or function predispose to both ID and psychiatric disorder. In both these cases, it is likely that the shared risk factors are having their effects primarily if not exclusively directly at the level of brain function, with ID

and psychiatric disorder being pleiotropic effects of the same risk factors/insults.

With respect to emotional and behavioral disorders, the greater family-based psychosocial adversity, indexed by reduced parental educational qualifications, lower socioeconomic status, and family poverty, partially but not fully accounts for the higher rate of psychiatric problems (Emerson & Hatton, 2007c; Emerson *et al.*, 2010a). As with medical/genetic factors, these psychosocial factors are known to be present before or shortly after the child's birth and therefore are unlikely to be caused by ID. However, the direction of effect is less clear with respect to the increased psychopathology (Dekker & Koot, 2003) and physical symptoms of stress reported in parents of children with ID (Smith *et al.*, 2012b). Some studies indicate parental psychiatric disorder is largely accounted for by family psychosocial adversity (Emerson *et al.*, 2010b) while others report that child behavior problems are a strong predictor of maternal distress (Hastings & Beck, 2004; Totsika *et al.*, 2011).

ID itself may increase the risk of psychiatric disorder. Decreased ability to communicate personal needs, understand the environment, and respond flexibly to varying situations may cause anxiety or oppositional, noncompliant behavior. Exposure to a range of additional adversities is increased in ID, including physical illness (Emerson & Hatton, 2007a), high parental expressed emotion (Beck *et al.*, 2004), peer relationship problems (Larkin *et al.*, 2012), and negative life events (Dekker and Koot, 2003; Owen *et al.*, 2004), including abuse and neglect (Horner-Johnson & Drum, 2006). The direction of effects among these associations, however, is poorly understood, and it is possible that some adversities are increased in response to difficult behavior, although this exposure may further increase behavioral problems.

Assessment of psychiatric disorders in people with ID

Many aspects of assessment and treatment overlap with those discussed in relation to individual disorders and what follows are the particular considerations that are distinctive in children with ID. Assessment should place developmental considerations at the core. It is essential to have a good understanding of a child's cognitive function, level and style of communication, and adaptive function to contextualize the patterns of behavior and emotions. If a formal cognitive assessment has not previously been undertaken, it should ordinarily be completed at this stage. The parent/carer's understanding of the child's level of functioning, the pattern and complexity of communication with the child, and the appropriateness of the educational placement should be identified. Enquiry about psychiatric symptoms should elicit specific descriptions, as many of the behaviors may be atypical. Emotional symptoms may be more difficult to identify when the child's communication ability is significantly impaired, and in such instances, observable

features of emotional disorders should be a prime focus. As in other populations, accounts of behavior in different contexts and a personal interview and/or direct observation of the child are essential. Judgments about the presence of symptoms should be made in the context of developmental (rather than chronological) age.

While the assessment should aim to identify psychiatric disorders as treatment targets, it should not exclude other causes of disturbed behavior, as described under behavior that challenges. The assessment should ascertain the presence of eating/feeding and sleeping problems, the role of coexisting physical disorders, especially brain-based disorders such as epilepsy, but also conditions that may cause pain, the presence of parental learning problems/ID and parental stress, psychosocial adversity, and support from statutory and voluntary services.

Assessing behavior in its context

A key element in the evaluation of behavior that challenges is the assessment of triggers or precipitants and reinforcement of maladaptive behaviors. Applied behavioral analysis is a rigorous, detailed, and quasi-experimental approach used by trained specialists, in the context of learning theory to understand the causes and modify the environment in order to reduce maladaptive behavior. In contrast, functional behavior assessment is a fundamental skill for all clinicians working in the field, to generate hypotheses about triggers and consequences that may provoke and reinforce behaviors. This involves obtaining a history of the antecedents and context, a detailed description of the behaviors and the response of others, both immediate and longer-term. Different behaviors should be evaluated separately. Information should include the effect of different settings, whether the onset was acute or insidious, and the relation to environmental changes or life events, whether there has been a change over time and, if so, whether it has been gradual or abrupt. When behavioral changes are sudden, particular consideration should be given to environmental changes, life events, physical conditions causing pain, and adverse effects of medication.

Assessment measures for psychiatric symptoms and disorders in ID

Many questionnaires and interviews designed for children of average ability are suitable in their *content* for children with mild ID. However, almost none of these has been normed on populations with ID and therefore use of the scores and cut-offs may not be valid (Simonoff *et al.*, 2013a). Standardized questionnaires may either exaggerate symptoms, for example, in children whose level of ID has not been recognized, or provide an underestimate, for example, when completed in specialist settings where most children have psychiatric problems. Therefore, they should be seen as an aid to comprehensive data-gathering and should not be used to rule in/exclude diagnosis.

In children with severe to profound ID, measures developed for the general population are often not suitable and instruments designed specifically for use in populations with ID are preferred. Several are widely used (Aman, 1986) and the Developmental Behavior Checklist in particular is both comprehensive in coverage and provides norms and subscales for the population with ID (Einfeld, 1995). Standardized child psychiatric diagnostic interviews, most commonly used in research, have not been modified for children with ID, although the Kiddie-SADS has been altered for people with ASD (Leyfer *et al.*, 2006). In general, the interviewer-based measures are sufficiently flexible to have face validity for populations with ID but will not include ID-specific behaviors. Typically developing younger children often have difficulty understanding key concepts in standardized interviews (Breton *et al.*, 1995) and this applies to a wider age range of people with ID, so informants are used more extensively. Strategies employed in assessing younger children (e.g., simpler language, visual prompts, checking understanding of concepts) are appropriate here. Tools specific for people with ID include the suite of measures comprising the Psychiatric Assessment Schedule for Adults with Developmental Disorders (PAS-ADD) (Moss *et al.*, 1998); these are designed to identify psychiatric conditions in adults, including affective and psychotic disorders. While intended for use with adults, their structure is useful in gathering accounts about behaviors that may indicate a severe mental disorder.

Other measures are available to assess behavior that challenges. The Challenging Behavior Interview measures the range, severity, and frequency of such behaviors (Oliver *et al.*, 2003). Both the Aberrant Behavior Checklist and Developmental Behavior Checklist have reported scores and subscales that are associated with behaviors that challenge (Einfeld & Tonge, 2002; Aman *et al.*, 2010). Other measures such as the Questions about Behavioral Function (Matson *et al.*, 1999) structure the functional behavioral assessment that aims to identify triggers for and consequences of behavior that challenges, which may increase its frequency or severity.

Differential diagnosis

There are two particular considerations with respect to differential diagnosis in people with ID. Developmental age should be considered in deciding whether symptoms are present, as behaviors may be abnormal for chronological but not for developmental age. On the other hand, care should be taken not to inappropriately ascribe psychiatric symptoms to ID itself, the well-documented process of “diagnostic overshadowing” (Jopp & Keys, 2001). This is best achieved by gaining careful accounts with behavioral descriptions and avoiding attributions.

Physical examination and investigations

If ID has not previously been diagnosed, the examination should include those elements that may identify an underlying cause, which may also shed light on psychopathology. With respect to behavior that challenges, examination should look for possible

causes of pain and adverse drug effects, such as akathisia or Parkinsonism. If treatment will involve pharmacotherapy, it is timely to evaluate for any physical contraindications, as people with ID are more likely to have congenital anomalies and other conditions that may limit therapeutic options.

Intervention

Most clinical trials have excluded those with ID, leaving a small evidence base. Treatment planning should ordinarily therefore follow recommendations for children of average ability. Behavioral interventions for challenging behavior, based on ABA principles, are often effective (Brosnan & Healy, 2011), although there is a very limited evidence base exploring when they should be used in combination with other approaches such as pharmacology (Brosnan & Healy, 2011). Psychological interventions for the emotional disorders in those with mild-to-moderate ID have not been adequately evaluated; using first principles, modifications should simplify language, reduce the need for abstract thinking, include visual materials, and review progress more regularly. Greater involvement of parents/carers is often helpful. In children with severe to profound ID or developmental age under about 7 years, behavioral interventions that are delivered by parents/carers and other adults are likely to be more effective. Principles should include clearly described, visually depicted expectations and reinforcers that are activated immediately when the behavior occurs, usually with short-term effects. It is important to identify reinforcers for the individual child, rather than relying on more generally used rewards and sanctions. For behaviors that occur in multiple settings, it is essential that a consistent approach is adopted in all domains.

Parents' needs should be addressed as there is a likely reciprocal relationship between child psychopathology and parental mental health and stress (Baker *et al.*, 2012a; Smith *et al.*, 2012b). Psychoeducation should be standard. The potential negative impact on siblings should also be considered (Neece *et al.*, 2010). Parents report wanting support, which may be provided by specific parent groups, and respite care, particularly when their child has mental health problems (Douma *et al.*, 2006).

With respect to pharmacotherapy, there is a small but consistent evidence base for treatment of ADHD in children with ID (Aman *et al.*, 2003; Simonoff *et al.*, 2013b) reporting reduced but significant effect sizes and higher rates of adverse effects. Medication should therefore commence at low doses with slow increases and frequent monitoring for both positive and adverse effects, wherever possible using rating scales. Children with ASD may be particularly sensitive to adverse effects but nevertheless can also experience benefit (Research Units on Pediatric Psychopharmacology (RUPP) Autism Network, 2005; Simonoff *et al.*, 2013b). Most of the trials assessing the use of antipsychotics in ASD include children with ID (Aman *et al.*, 2005; Marcus *et al.*, 2009); although the results have not been stratified for IQ, it is reasonable to consider that risperidone

and aripiprazole can significantly improve irritable, aggressive behavior in this group. One trial comparing risperidone alone and with parent training showed that the combined intervention led to the use of lower doses of medication and slightly greater behavioral improvement than risperidone alone (Scahill *et al.*, 2012). The results need replication and generalization to other treatments, but provide an appealing model for multimodal intervention. In the absence of an evidence base for pharmacological interventions in other disorders, clinicians should use the principles described above for stimulants.

As multiple psychiatric problems/disorders are frequent in people with ID, polypharmacy (the excessive use of multiple medications) is common (Holden *et al.*, 2004; Haw & Stubbs, 2005; Tobi *et al.*, 2005). However, it should be avoided whenever possible because of the increased susceptibility to adverse drug effects. Several steps may help minimize the use of multiple drugs. First, the target symptoms should be carefully identified, prioritized for treatment, and linked to an underlying psychiatric disorder or evidence-based intervention. Second, baseline information on severity, frequency, and duration should be obtained, using either a standardized or bespoke measure. Regular monitoring of change should use the same scale, along with a systematic enquiry about adverse effects. If no or inadequate response occurs, compliance should first be checked and consideration given to whether the dose can be increased. In evaluating possible adverse effects, the clinician needs to balance up the increased susceptibility of this population against variation in the client's behavior; certain potential adverse effects, such as irritability, aggression, and mood changes, may reflect variation in the child's behavior for other reasons. When treatment response remains inadequate despite therapeutic doses, the diagnostic hypothesis should be reviewed before initiating an alternative medication.

Other nonspecific elements of intervention for children with ID include enhancement of communication, adaptive function, and social skills, which, in adults, can improve community participation (Woolf *et al.*, 2010). These are often best undertaken in the school setting. The suitability of the educational placement should be considered, with a view to whether it is meeting both academic and emotional/behavioral needs, and whether the school is able to support the recommended interventions. Arrangements vary both locally and nationally, but all children with ID and a psychiatric disorder should have additional educational support. The overwhelming majority of children with severe/profound ID will be best placed in specialist schools catering for their educational and mental health needs.

Input from social services and the voluntary sector should also be addressed in the management plan. The needs of children and their families for respite care vary widely but families should be aware of the range of options. Often, voluntary organizations, including disorder-specific societies, offer a range of information and support for both parents and children. Social care and voluntary agencies may also help by increasing access to community activities for children and young people with ID.

Mental health services for children and adolescents with ID

The successful delivery of mental health services for children and adolescents with ID depends not only on the expertise of mental health clinicians within that service but also on the configuration of supporting health, education, and social services. Different models operate across and within national boundaries (Anagnostopoulos & Soumaki, 2011; Ispanovic-Radojkovic & Stancheva-Popkostadinova, 2011; Kwok *et al.*, 2011; Lin & Lin, 2011) and there is an absence of research that identifies preferred service models. However, some principles can be distilled to guide service organization. First, the rights of people with disability to equal access to services (among other rights) has been established in a large number of documents, including the Human Rights Act (1998) and the World Report on Disability (Emerson, 2012), as well as national documents such as the United Kingdom's National Service Framework (Department of Health, 2004). Second, approximately 15% of the child and adolescent population with mental disorders have ID, most of which are mild (Emerson & Hatton, 2007b), constituting a significant minority of those requiring provision. Furthermore, in many (but not all) countries, children and adolescents with mild ID attend mainstream schools and the links that services have with local schools would equally apply to children with ID. Third, the population requiring highly specialist mental health services are those with significant communication problems, severe or profound ID, unusual behavioral phenotypes and significant behavior that challenges, which is a much smaller group. Fourth, the effective function of mental health services for this population requires collaborative relationships with services in physical health, education, and social services, as well as adult mental health (both with respect to transitional arrangements for adolescents and also to provide services for parents). Fifth, consideration should be given to the accessibility of inpatient psychiatric units with the professional skills and appropriate environment to assess and treat patients with significant levels of ID. In units without these qualities, children and adolescents are often misdiagnosed, for example, as having a psychotic disorder when their communication is idiosyncratic or difficult to understand. Sixth, while there are no agreed standards, the mental health services should include professionals from a range of backgrounds and trained to work with children and adolescents with ID; psychiatry and psychology and psychiatric nursing/behavior therapy are essential for outpatient care and there should be access to team members who have the skills to work with families and speech/language and occupational therapists. In terms of wider relationships, mental health services should develop links with paediatricians, clinical geneticists, physiotherapists, specialist teachers/educational psychologists and social workers. Seventh, the model of care often practiced in mental health services, in which treatment for an episode of illness is followed by discharge, may not be optimal for children with ID, whose mental health problems

can be chronic. Some children and their families may benefit from predictable reviews, even if these are infrequent. Eighth, in a climate of inclusion and de-institutionalization, day and residential education and care in specialist settings should not be viewed necessarily as indicating a failure of services; rather the focus should be on reducing behavioral and psychiatric disorder and optimizing well-being and quality of life for the child and family. Specialist care may be the best choice for children with significant ID and/or behavior that challenges, when both child and family-wide outcomes are considered (Brown *et al.*, 2011).

Special issues in mental health and ID

Children and adolescents with ID and the criminal justice system

The literature on prevalence of ID among adult prisoners is generally of low quality and mixed in its findings (Fazel *et al.*, 2008); in contrast, one birth cohort study clearly demonstrates increased criminality among adults with ID (Hodgins, 1992). Systematic studies of young people in the criminal justice system report that youth with IQs in the mild ID and borderline range are overrepresented (Farrington & Loeber, 2000; Herrington, 2009), although rates of identification vary widely (Hodgins, 1992; Sondenaa *et al.*, 2008; see Chapter 49). It appears that those with more severe ID are protected by greater levels of community supervision, a reduced range of activities and social interaction, and also by intervention from carers when they come into contact with the criminal justice system (Lyll *et al.*, 1995). Factors associated with ID that probably increase the likelihood of juvenile offending include behavioral problems and autistic symptoms (Douma *et al.*, 2007; Geluk *et al.*, 2012), as well as the increased likelihood of detection.

Young people with ID are also more likely to be the victims of crime (Petersilia, 2001) and other forms of maltreatment (Horner-Johnson & Drum, 2006; Turner *et al.*, 2011). Furthermore, they are perceived as poor witnesses and as being more suggestible (Gudjonsson & Henry, 2003; Manzanero *et al.*, 2012), and this may influence the willingness of authorities to prosecute.

Parents with ID and their parenting

With changing attitudes to disability, de-institutionalization, and the Human Rights Act, many societies now recognize the desire of adults with ID to become parents and are beginning to investigate their needs and those of their children (O'Keeffe & O'Hara, 2008). Estimated rates of ID among parents vary widely and formal identification is likely to prove an underestimate (Department of Health and Department for Education and Skills, 2007; Weiber *et al.*, 2011). Most research involves families who have come to the attention of services, so generalizability of the findings is uncertain. These studies indicate increased risk of neglect among children (Feldman, 2002). Parents with ID have high rates of psychopathology and previous childhood

abuse and trauma (McGaw *et al.*, 2007) and these factors are linked to professional concern about their parenting (McGaw *et al.*, 2010; Azar *et al.*, 2012; see Chapter 28). Mothers with ID may also be more prone to have antisocial (often without ID) male partners (McGaw *et al.*, 2010).

Once concerns have reached the judicial system, children are more likely to be removed from their birth parents and subsequently placed for adoption (Booth & Booth, 2004). Recent modifications of parent training programs to meet the needs of parents with ID have been evaluated and early results are promising (Coren *et al.*, 2010; see Chapter 37).

Future developments and necessary research

Research and clinical advances in ID have lagged behind those in other areas of child and adolescent psychiatry. There has been a tendency to assume “one size fits all” and that clinical advances in other areas can be directly applied to children with ID; where the evidence is available, this is not at all the case. Substantial work is required in all domains to reach the same level of care for this population, but key priorities can be identified.

Prevention of ID and service development in low- and middle-income countries

While considerable progress has been made in high-income countries in prevention and early intervention to reduce the incidence of ID, many of these advances have not been translated into care in poorer countries, which are actually less well-equipped to support people with ID. However, research suggests that such programs, for example, to provide genetic screening and improve obstetric optimality, can be delivered and are successful in reducing ID (Dave *et al.*, 2005). Research should focus on effective and cost-effective prevention strategies.

Improved tools for assessing mental disorder in ID and quantifying outcome

There are few available validated measures of psychopathology for those with ID, which limits other clinical and scientific advances. The problem is most acute in relation to self-report measures, for unusual behaviors, and in measuring outcomes. Furthermore, many of the currently available measures do not map well to recognized mental disorders and therefore are not helpful in guiding intervention. Efforts should include developing and modifying instruments that are aligned with recognized conditions and allow evaluation of treatment response. As diagnostic and predictive biomarkers become available, these may be particularly useful in populations with ID and therefore need evaluation in this group.

Interventions trialed for children and adolescents with ID

The current state of affairs, in which the accruing literature on treatment efficacy and effectiveness excludes people with ID, is

unacceptable, given that this group represents 15% of the mental health burden. Pharmacological trials indicate significantly reduced effect sizes for conventional interventions in children with ID but the reasons for this are unclear. More experimental approaches to pharmacological trials (e.g., different treatments) can help understand this phenomenon. Psychological interventions need modification and robust testing (including blinded outcome measures).

New technologies and ID

Developments in computer technology make the software increasingly flexible and easy to use. The modification and development of software for people with ID could enhance their communication, promote independence and adaptive function, and complement educational methods.

Treating ID: how far away are we?

The genetic advances over the past two decades in identifying causes of ID have been immense. The gap is closing between gene identification, understanding of function, and intervention and promising early work with animal models will eventually translate into treatments for humans. Although ID is especially challenging for intervention, this area holds promise for conditions caused by single mutations.
